Preface

The *Encyclopedia of Membranes* is a reference work that covers all aspects of membrane science and technology, from basic phenomena to the most advanced applications and future perspectives. It is aimed at students, graduate students, academic and industrial researchers, and practitioners.

The *Encyclopedia of Membranes* is organized around a list of searchable *Entries* or *Terms*, in alphabetical order, giving the user fast and easy access to terminology, description, theory, and application of membrane science.

Entries range from one to several printed pages and are written by one or multiple authors.

Authors are both from academic institutions, research agencies, and industries.

The development of the Encyclopedia is undertaken by the Chief Editors, Prof. Enrico Drioli and Dr. Lidiatta Giorno, responsible for the selection of the topics, the terms, and the quality of the contributions. An Advisory Board was identified to discuss major items and promote holistic vision of the work. An Editorial Board assisted the Chief Editors in their activities.

The *Encyclopedia of Membranes* is a landmark work covering the science, technology, and application of membranes, membrane operations, and related fields.

A membrane is a nanostructured/functionalized thin barrier that controls the exchange phenomena (matter and energy) between two different phases, both through the external forces and under the effect of fluid properties, and also through the intrinsic characteristics of the membrane material itself.

Membranes are used in various applications. They differ widely in their structure, in their function, and the way they are operated. Membranes may be biological or synthetic, solid or liquid, homogeneous or heterogeneous, isotropic or anisotropic, and it can be a fraction of a micrometer or various millimeters thick. The application of different membrane structures and driving forces caused a number of rather different membrane processes such as micro-, ultra-, and nanofiltration, reverse osmosis, dialysis and electrodialysis, pervaporation, gas separation, membrane contactors (membrane distillation, membrane crystallizer, membrane strippers, membrane scrubbers, membrane condenser, membrane emulsifier), membrane reactors, catalytic membrane reactor, etc.

In various fields, membrane operations are already dominant technologies. Interesting examples are in the seawater desalination, in wastewater treatment

and reuse, and in biomedical applications. They are of interest in all sectors strategic for a sustainable development. They are clean, safe, require low energy input, and suitable to promote process intensification. Practically all typical unit operations of process engineering might be redesigned as *membrane unit operations*.

Membrane operations are largely present, for example, in the following fields:

- *Water treatment and purification*
- *Energy*
- *Gas separation*
- *Solvent treatment and purification*
- *Petrochemical industry* (where the integration of different membrane operations has promising applications)
- *Environment*
- *Agro-food and packaging*
- *Biotechnology*
- *Tissue engineering and regenerative medicine*
- *Biorefinery*
- *Pharmaceutical and cosmetic*
- *Microelectronics (OLEDS)* (which is becoming an area of interesting applications)

Other fields that will exploit more and more membranes' unique features include:

- *Sensors*
- *Micromanufacturing*
- *Responsive materials*
- *Safety and security*
- *Space*

The large spectrum of challenges membrane operations contribute to face today and their strong multidisciplinary character suggested to develop this work on membrane science and membrane engineering.

Enrico Drioli
Lidietta Giorno

Acknowledgments

We are very pleased to acknowledge the important help and contribution received by our colleagues Adele Brunetti, Enrica Fontananova, Francesca Macedonio, and Rosalinda Mazzei, in the preparation of this Encyclopedia. Their continuous collaboration in keeping all necessary contacts with hundreds of colleagues from all around the world, in discussing on the various unexpected problems for finalizing this work, has been significant. Thank you!

We also wish to express grateful thanks to the members of the advisory board for their kind availability as well as to all authors for their invaluable contribution to the work.

Enrico Drioli
Lidietta Giorno

Editors Biography

Enrico Drioli Emeritus Professor, University of Calabria, Rende, Italy

Career

Distinguished Visiting Professor, Faculty of Engineering and Information Technology, University of Technology Sydney, Australia (January 2016)

Distinguished Adjunct Professor, Center of Excellence in Desalination Technology, King Abdulaziz University, Jeddah, Saudi Arabia (2012)

WCU (World Class University) Distinguished Visiting Professor, Department of Energy Engineering, Hanyang University, Seoul Korea (2009)

Emeritus Professor, School of Engineering of the University of Calabria (2012)

Professor of Chemistry and Electrochemistry at the School of Engineering of the University of Naples (since 1968–1982)

Professor at the School of Engineering of the University of Calabria (1981–2011)

Dean of the School of Engineering of the University of Calabria (1982–1985)

Founding Director of the Institute on Membrane Technology (ITM) of CNR (from 2011)

Director of the Institute on Membranes and Chemical Reactors of the National Research Council (1993–2001)

Director of the Institute on Membrane Technology (ITM) of CNR (2002–2008)

Research Interest

Membranes in artificial organs, integrated membrane processes, membrane preparation transport phenomena, membrane distillation and membrane contactors, catalytic membrane, and catalytic membrane reactors.

Biography

Coordinator of the European Erasmus Mundus Doctorate in Membrane Engineering (EUDIME).

Scientific Coordinator of various international contracts/agreements: ITM-CNR-KACST, Hydrophobic membrane preparation for membrane contactors application; ITM-CNR-KISR (Kuwait Institute for Scientific Research), Evaluation of the potentialities of the membrane distillation technology for desalting de-oiled filtered high concentrated saline waters; RHODIA; etc.

Member of the Scientific Advisory Panel (SAP) for the KAUST Water Desalination and Reuse (WDR) Center from 2010

MIAC International Award for International Collaboration and Promotion (October 2015)

Award with the Academician Semenov Medal of Russian Academy of Engineering Science (2014)

Honorary Membership of the Czech Society of Chemical Engineering (2012)
2011, “Richard Maling Barrer Prize” of the EMS, for his “outstanding contributions to membrane science and technology”

2009, Doctorate Honoris Causa from University of Paul Sabatier of Toulouse, France

2005, International Cooperation Honor Award, Membrane Industry Association of China (MIAC) for special dedication to International Cooperation between China and Europe in the field of membrane science and technology

2005–Present, Guest Professor, Jiangsu Polytechnic University, China

1999, Honorary President, European Membrane Society

1992, Doctorate Honoris Causa in Chemistry and Chemical Technology, Russian Academy of Science

1991, Honorary Professor, China Northwest University in Xi'an, Shaanxi, China

1982–1998, President, European Society of Membrane Science and Technology (European Membrane Society)

Advisory Board of *Journal of Membrane Science*, *Polish Journal of Chemical Technology*; Editorial Board of various other international scientific journals.

Executive Editor: *Applied Water Science* Journal, Springer Berlin Heidelberg (Germany) and *Membrane Water Technology*, Techno Press (Korea).

Editor of more of 750 scientific papers, 22 patents, and 24 books

Lidietta Giorno is serving as the Director of the Institute on Membrane Technology of the National Research Council of Italy, ITM-CNR, since 2009.

Her research expertise include membrane bioengineering, biocatalytic membrane reactors, integrated membrane systems for bioseparations and bioconversions, downstream processing based on molecular separation, membrane chirotechnology, membrane emulsifier, and integrated membrane operations for water treatment. She has been involved in membrane science and engineering research and development for some 25 years, and in research cooperations at European and international levels.

She was awarded the international “Guido Dorso Award” for research in 2011, sponsored by the Italian Senate and the University of Naples Federico II. She was awarded the Sapio Red Carpet Award in 2016 among female scientists of highest scientific profile who are engaged for the development of the country.

She worked abroad in the USA at Sepracor Inc. in 1992, in the Netherlands at ATO-DLO in 1994, and in France at The University of Compiègne in 1997–2000. She is Visiting Professor at Tianjin University of Science and Technology, China, since 2008.

Lidietta Giorno is coeditor of 8 books, over 110 peer-reviewed scientific papers in international journals, and coeditor of the *Encyclopedia of Membranes*, Springer, 2016. She is member of the editorial board of scientific journals, member of the referee pool of scientific journals and research agencies, and member of international committees and several scientific societies.

She has served as member of the Board of Directors of the European Membrane House (EMH, Belgium), formed to continue the activity of the NanoMemPro Network of Excellence funded by the European Commission within the FP6.

She has served on the European Membrane Society Council as the President of the EMS Council and the Editor of the EMS Membrane Newsletter. She was nominated Honorary Member of the European Membrane Society in 2014.

Ab Initio Calculation

Giorgio De Luca

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Although the term *ab initio* usually indicates calculations based on first principles, either they are related to classical or to quantum mechanics, this term is generally used when it refers to calculations based on quantum mechanics first principles (Szabo and Ostlund 1994). Thus, if the d'Alembert equation is used to describe a force balance, in which the expression of the forces is only expression of chemical-physical average properties (values obtained as average of microscopic properties) without any use of empirical adjustable parameters, the calculation can also be defined *ab initio*. As mentioned, in general, the term *ab initio* is used when the calculations are performed by using the Schrödinger equation or rather an eigenvalue equation for the quantum system. However, attention must be paid to the quantities or potential operators that define the eigenvalue equations. In fact, if the operators in the Hamiltonians are defined using experimental data or by means of fitting procedure, then the calculation should not be defined *ab initio* but semiempirical (Clementi and Corongiu 1995). The density functional theory (Parr and Yang 1989) is a controversial case, since in principle,

it is an *ab initio* theory, but various potentials defining the quantum system are obtained by using empirical data. For example, hybrid potentials are linear combinations of pure potentials. The coefficients of the linear combinations are obtained using experimental data. Nevertheless, other potentials are obtained from the thermodynamic theory of electron gas (statistical thermodynamics); thus the latter can be considered *ab initio*. For this reason also the density functional theory is considered an *ab initio* methodology. Summarizing, two broad theoretical methods can be identified: those that make use of adjustable parameters that should be to be defined each time, *ad hoc*, depending on the system studied and those that do not use *ad hoc* parameters which only refer to the first principles and are known as the *ab initio* methods.

Particular attention should be given on multiscale simulations in which parameters provided by sub and nanoscales are used in meso and macro scales without resort of empirical-adjustable parameters. Even these types of calculations can be defined *ab initio*. (De Luca et al. 2014) recently, have used different approaches, ranging from quantum mechanics to macroscopic models, to simulate the formation of the protein cake on a membrane surface and the consequent decay of water flux. Although various parameters were calculated *ab-initio* others have not yet been assessed in this way; however, this work represents one of the first attempts of an *ab-initio* simulation of a membrane process.

Acetic Acid Dehydration by PV

Nora Jullok

School of Bioprocess Engineering, Universiti Malaysia Perlis (UniMAP), Arau, Perlis, Malaysia

Acetic acid is an important organic chemical used in a wide range of applications worldwide. Among others, it is used as a raw material in the synthesis of vinyl acetate monomer (VAM) for the production of a wide variety of polymers. These include polyvinyl acetate, polyvinyl alcohol, polyacetals, and ethylene vinyl acetate copolymers (Minardi et al. 2002). A regular distillation process to dewater acetic acid is known to be energy intensive and to incur high operational costs. Since the separation of acetic acid from water using distillation is far from being the best process, any cost-efficient method to dehydrate acetic acid is in demand. Among these alternative methods, **pervaporation** has been suggested as a promising solution to separate acetic acid aqueous solutions (Algezhawi et al. 2005; Durmaz-Hilmioglu et al. 2001; Huang et al. 1988). Pervaporation is a membrane-based process that can be potentially applied to purify acetic acid (i.e., via **acetic acid dehydration**). It requires the availability of a system with a vacuum downstream to enable separation by partial vaporization through a dense, selective membrane. The permeation of a permeating component can be described in five consecutive steps: (1) sorption on the

membrane surface, (2) liquid diffusion through the membrane matrix, (3) vaporization, (4) vapor diffusion, and (5) vapor desorption (Van der Bruggen 2009). Several studies have been undertaken on dehydration of acetic acid-water mixtures using organic, inorganic, and composite membranes. It has been shown that inorganic membranes, in most cases, are capable to provide a very high selectivity of water, which penetrates through the membrane, but with a very low permeate flux, e.g., using zeolites. In an acid-proof silicalite-1 zeolite study, it was found that the separation factor was near infinite (Masuda et al. 2003). A study using free-radical graft polymerization of 1-vinylimidazole (VI) onto the as-synthesized mordenite zeolite membrane in acetic acid dehydration has been conducted by (Chen et al. 2010). It was found that by applying this membrane in pervaporation at higher temperature, it yields a higher flux and also a higher selectivity. Another interesting study was the investigation by Teli et al. (2007) on applying a silicotungstic acid incorporated sodium alginate (STA-NaAlg-5). This study gave an excellent separation factor and flux, ranging from 0.194 to 0.489 kg/m² h. However, the membrane performance decreased when applied at high temperature and in a more dilute feed solution. As the temperature and water content in the feed solution are increased, the flux increases and selectivity decreases. Other than inorganic membranes, polymeric membrane shows promising solution. Pervaporation up to 90 wt.% acetic acid using polyphenylsulfone membranes at temperature range from 30 to 80 °C exhibited high flux, good separation factor, and membrane stability (Jullok et al. 2011). The plasticizing effect was postulated to result in a special sieving property, which assisted the water molecules to be transported across the membrane matrix.

Acetic Acid Dehydration by Pervaporation with Charged Membranes

Nora Jullok

School of Bioprocess Engineering, Universiti Malaysia Perlis (UniMAP), Arau, Perlis, Malaysia

Acetic acid is produced both synthetically and biologically. The synthetic production typically uses the Monsanto process, which is also known

as methanol carbonylation for acetic acid synthesis. About 75 % of acetic acid in the chemical industry is produced by this process, in which carbon monoxide reacts with methanol under influence of a rhodium complex catalyst at 180 °C and pressure of 30–40 atm (Shen et al. 2011). The main challenges in acetic acid and water separation are (1) cost minimization and (2) optimizing separation efficiency. In acetic acid aqueous solutions, there is a dynamic equilibrium between neutral molecules and the acetate and hydronium ions. It was observed that acetic acid dissociation is not only driven by the breaking of H-bonds connecting the ions but also triggered by a solvent reorganization around the proton-accepting water (Park et al. 2006), as illustrated in Scheme 1. Water molecule forms four hydrogen bonds, whereas a hydronium ion only forms three. Due to the proximity of the boiling point between acetic acid and water, separation using conventional methods may not be the best choice to consider. **Dehydration of acetic acid by pervaporation with charged membranes** can potentially be applied. Ion exchange membranes are pictured as porous with charges lining the pore walls. An example of ion exchange membrane used for this specific application is Nafion 117, which has been modified to form Nafion (C₈H₁₇)₄N⁺. Other ion exchange membranes which have been evaluated include sulfonated polysulfone (PSF(SO₃[−])-H⁺) and cross-linked styrene-co-butadiene base. They are mechanically stabilized with poly(vinyl chloride) baking and contain quaternary ammonium and sulfonic acid moieties, respectively (AMV-CH₃OO[−] and CMV-H⁺). The interaction of polymers with water is strongly influenced by the fixed ion and counterion. Hydrogen-bonding, dipole-dipole, and ion-dipole are the three possible interactions between water molecules and membrane surface. As the interaction between fixed ion and counterion with water increases, the sorption selectivity to water increases. A polymer having H⁺ as counterion has a lower water sorption and lower water sorption selectivity compared to a polymer having metal counterion. Besides, H⁺-containing polymer also has a high permeability but low separation factor. On the other hand, for a similar

Acetic Acid Dehydration by Pervaporation with Charged Membranes,

Scheme 1 Dissociation of acetic acid in water

polymer, which has a metal counterion, pervaporation shows lower permeability but higher separation factor (Semenova et al. 1997).

Acetic Acid Dehydration by Pervaporation Zeolite Membranes

Reyes Mallada

Department of Chemical and Environmental Engineering and Aragon Nanoscience Institute, Universidad de Zaragoza, Zaragoza, Spain

The best performance in pervaporation for water dehydration corresponds to zeolite A, which is the zeolite with the lowest Si/Al ratio (equal to 1) and therefore the highest hydrophilicity. However, the high aluminum content of this zeolite makes it unstable under acidic conditions and it dissolves at low pH.

The separation of water in the presence of acetic acid or other acids could be important in the case of membrane reactors, active zeolite membrane reactors (AZMRs), for equilibrium displacement (see also Membrane reactor equilibrium conversion and Pervaporation membrane reactor). The esterification reaction using acid produces water that could be

removed continuously using a water permeable acid resistant membrane.

The most promising results concerning separations in acid medium have been obtained with zeolites with a moderate Si/Al ratio such as zeolite T with Si/Al = 4 or mordenite with Si/Al ratio from 7 to 20. Both zeolites have been tested in water/acetic acid mixture (50/50 wt.%) showing stability after the exposure to this mixture at mild temperature around 70 °C for several days.

Although the performance of these zeolites in pervaporation for water dehydration are lower compared to zeolite A (Arruebo et al. 2008), the acid stability of these zeolites is higher than that of zeolite A and makes them good candidates for the separation of acid mixtures. The researchers of Mitsubishi studied the technical feasibility of mordenite membranes for dehydration of acetic acid aqueous solution with a feed rate of 1000 kg h⁻¹. Their results suggested that the developed mordenite membrane deserved to the further technically developments of up-scale and mass-production (Sato et al. 2011). The membrane performance in pervaporation was measured in a feed mixture of water (50 wt.%) / AAc (50 wt.%) to be 10.9 kg m²/h for permeate flux and to be 0.77 × 10⁻⁶ mol m²/sPa for water permeance with separation factor of 500 at 130 °C.

Acid Gas: Effect on Membrane Properties

Colin A. Scholes

Department of Chemical and Biomolecular Engineering, University of Melbourne, Parkville, VIC, Australia

Acidic gas removal is the largest application of gas separation membranes and a vital process in the natural gas processing industry. Membranes used in this process are designed to separate H₂S and CO₂, and this process is known as natural gas sweetening. This is readily required for low-quality natural gas reserves, which need to be processed to achieve pipeline specifications of CO₂ <2 mol% and H₂S <4 ppm (Baker 2001). The removal of acidic gases is also required for biogas and gasification, where H₂S and CO₂ are separated from CH₄, CO, and H₂. For natural gas sweetening, the membrane must exhibit high permeability for H₂S and CO₂, with a large selectivity relative to methane.

In general, nonporous polymeric membranes are applied in acidic gas removal, taking advantage of the solution-diffusion mechanism and the high solubility of H₂S and CO₂, compared to CH₄. Also polymeric membranes almost always demonstrate selectivity for H₂S over CO₂, again because of the higher condensability of H₂S compared to CO₂, as demonstrated by the difference in critical temperature. Table 1 provides the H₂S permeability and H₂S/CO₂ selectivity for a range of polymeric membranes. The study of porous membranes for acidic gas removal is limited,

even though both H₂S and CO₂ have smaller kinetic diameters than CH₄. In the natural gas sweetening industry, both cellulose acetate- and polyimide-based membranes have been commercialized.

Prolonged exposure to both H₂S and CO₂ can lead to plasticization and degradation of the polymeric membrane over time. This is because the acidic nature of the gases means they will readily interact with the polymeric chains, disrupting chain packing and lubricating polymer chain motion, resulting in more rubbery behavior. Membrane degradation by these gases is greatly enhanced if water is present, because of the weak acidic dissociation of these gases (Scholes et al. 2009).

For inorganic and metallic membranes, H₂S is of particular concern, because of the effect sulfur can have on the membrane material (Lu et al. 2007). A good example of this is in H₂ separation with Pd-based membranes. The presence of H₂S leads to membrane brittleness and performance degradation because of lattice expansion on the formation of Pd-S. Hence, in applications such as gasification, it is necessary for the gas to have H₂S removed prior to the gas separation membrane, use sacrificial layers, or add sulfur-resistant materials.

Chemical Thermodynamics

Depending on a specific area of fundamental science and technology, the term “activity” may have a different meaning. For example, in chemical thermodynamics, activity (a) is well known as a convenient variable to represent data, obtained experimentally or calculated theoretically, for the values of chemical potentials of components in real chemical solutions. For the i – th component of a mixture, activity a_i is defined as follows: $\mu_i = \mu_i^0 + RT\ln(a_i)$, where μ_i is the chemical potential of a component and μ_i^0 is the chemical potential of that component in standard state. R is the gas constant and T is the thermodynamic temperature. The numerical value of the activity depends on the choice of a standard state, as it describes the difference between an actual chemical potential and a standard chemical potential.

Fuel Cells and Electrocatalysis

In hydrogen fuel cell science and technology, activity is often referred to as the measure of efficiency of electrocatalysts. Electrocatalytic processes in fuel cells occur on the surface of electrodes, and one of the main challenges is to explain, predict, and improve electrocatalytic activity of various electrode materials. In the area of low temperature PEM (proton exchange membrane, also called polymer electrolyte membrane) fuel cells, catalytic activity is often used to compare efficiency of electrocatalysts toward kinetics of the oxygen reduction reaction (ORR) occurring at the cathode. ORR is known to have slow kinetics due to the reaction having multiple steps and difficulties in breaking the O–O bond, which leads to a larger

cathodic overpotential (Zhang 2008). In this case, overpotential is defined as the extra potential over the equilibrium value that must be applied to cause an electrode reaction at a certain rate. Thus, an electrocatalyst with high activity is required to minimize the overpotential.

According to the Sabatier principle (Bligaard et al. 2004), a volcano-shaped curve is obtained when the activity of a catalyst for ORR is plotted as a function of a variable that relates to the ability of the electrocatalyst surface to form chemical bonds with oxygen, reaction intermediates, and/or products (Nørskov et al. 2004). For example, it was shown that the catalytic activity of a single Pt-based electrocatalyst toward ORR depends strongly on such variables as the O₂ adsorption energy, the dissociation energy of the O–O bond, and the binding energy of OH on the catalyst surface. The electronic structure of the Pt catalyst (Pt d-band vacancy) and the Pt–Pt interatomic distance (geometric effect) can strongly affect these variables. Theoretical calculations on O₂ and OH binding energy on several metals have predicted that Pt should have the highest electrocatalytic activity among other metals with the ORR activity of Pt > Pd > Ir > Rh, which is in agreement with experimental results. Calculations have also predicted that Pt–M (M = Fe, Co, Ni, etc.) bimetallic alloys should have higher catalytic activity than pure Pt, which has again been proven by experiments (Nørskov et al. 2004).

Practical Measurements

Practically, electrocatalytic activity of various electrocatalysts can be compared by measuring electrical currents produced at a given overpotential. The electrocatalyst that generates higher current at lower overpotential is generally a better electrocatalyst.

The rotating disk electrode (RDE) technique is often used to measure ORR activity of electrocatalysts for hydrogen PEM fuel cell applications. Typically, current density j is measured at 0.9 V at the positive voltage sweep at a certain electrode rotating speed. The measured current

density j is expressed by the following equation: $\frac{1}{j} = \frac{1}{j_k} + \frac{1}{j_d} + \frac{1}{j_f}$, where j_k is kinetic current density, j_d is hydrodynamic diffusion limiting current density, and j_f is film diffusion limiting current density. RDE experiments should be designed to maximize j_f . In that case, $\frac{1}{j} = \frac{1}{j_k} + \frac{1}{j_d}$ and after rearrangement $j_k = j \times j_d / (j_d - j)$.

For ORR the value of j_d is normally taken at 0.4 V during RDE experiments.

Once j_k is known, activity is often reported in practical values as mass activity (A/mg Pt) by normalization to the value of Pt loading of the sample on the disk electrode.

Another practically important way of reporting the electrocatalyst activity is to use area-specific activity. The area-specific activity, expressed in the following units, $\mu\text{A}/\text{cm}^2$ Pt, is reported by normalization of j_k to the electrochemical surface area (ECSA) of the catalyst.

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Synonyms

Membrane artificial organs

Acute kidney injury (AKI) or acute renal failure indicates kidney injury from less severe forms of injury to more advanced injury when acute kidney failure may require renal replacement therapy. Acute kidney failure occurs when kidneys lose their functions that include excretion of wastes, acid-base homeostasis, osmolality regulation, blood pressure regulation, and hormone secretion (Waikar et al. 2008). When kidneys lose their filtering ability, dangerous levels of wastes may accumulate, resulting in an increasingly toxic blood stream and fluid overload. Acute kidney failure requires replacement therapy that includes: hemodialysis, peritoneal dialysis, hemofiltration, hemodiafiltration, and renal transplantation. Dialysis treatment involves the diffusion of solutes through a semipermeable membrane driven by a concentration gradient. For the treatment of uremic patients, an artificial membrane (hemodialysis) or a biological membrane (peritoneal dialysis) can be utilized. The membrane-based treatments involve pumping patient's blood from the body through a membrane device that acts as an artificial kidney by separating waste products including toxins and excess water from the blood. The therapies for the treatment of patients with acute renal failure are not limited to dialysis but rather include other modalities. Hemofiltration has been developed to overcome the reduced efficacy of diffusion for molecules with middle and large MW. In this process the driving force is a hydrostatic pressure gradient that induces a large flux of water across the membrane from blood side to the filtrate side. As a result the rate of solute removal is proportional to the applied pressure. Hemodiafiltration is the combination of hemodialysis and hemofiltration processes. The high rate of ultrafiltration is combined with the efficient diffusion overcoming the disadvantages related to each single treatment.

Addition Norbornene Polymer-Based Membrane Materials

Yuri Yampolskii

A.V. Topchiev Institute of Petrochemical
Synthesis, Russian Academy of Sciences,
Moscow, Russia

Substituted norbornenes and tricyclononenes can be polymerized according to the addition scheme, that is, via opening of the double bonds of these cycloolefins (Finkelshtein et al. 2011; Yampolskii 2010).

The resulting glassy polymers have very rigid main chains and high glass transition temperatures. The gas permeation parameters of the obtained polymers strongly depend on the substituents in the monomer molecules. Thus, nonsubstituted addition polynorbornene (PNB) is a relatively low-permeability polymer ($P(\text{O}_2) = 11$ Barrer), though when substituents are introduced permeability increases markedly (Fig. 1). In particular, methyl-substituted PNB has $P(\text{O}_2) = 89$ Barrer, while for the polymer with bulkier, SiMe_3 substituent, the permeability is further strongly enhanced ($P(\text{O}_2) = 980$ Barrer) (Yampolskii 2010). SiMe_3 -substituted PNB and poly(tricyclononenes) reveal large free volume according to the positron annihilation lifetime spectroscopy and solubility-controlled selectivity in separation of hydrocarbons (Finkelshtein et al. 2011; Gringolts

et al. 2010): permeability coefficients increase for penetrants with larger size or molecular mass (e.g., butane). This makes them important candidates for membranes for separation of natural and associated petroleum gas, especially because their gas permeation parameters are relatively stable in time in comparison with highly permeable polyacetylenes. These polymers are soluble in various organic solvents, so high-flux composite membranes (permeance of about $5\text{--}15 \text{ m}^3(\text{STP})/\text{m}^2 \text{ h bar}$) can be prepared from them.

Adhesion to Membrane Surfaces

Li-Ping Zhu

MOE Key Laboratory of Macromolecular
Synthesis and Functionalization, Department of
Polymer Science and Engineering, Zhejiang
University, Hangzhou, China

Adhesion to membrane surfaces generally describes the sticking or holding fast of some substances such as paints, cells, platelets, bacteria, proteins, etc. on membrane surfaces when they are in contact. Usually, the intermolecular interaction is responsible for the adhesion of substances on membrane surfaces (Huang et al. 1999). The

adhesion can be divided into several categories, including mechanical adhesion, chemical adhesion, dispersive adhesion, electrostatic adhesion, and diffusive adhesion according to the forces that cause adhesion. The adhesion is a stronger interaction between unlike substances than adsorption (Jacek et al. 1999). In the filtration operation using a membrane, the adsorption and adhesion of foulants such as colloids, particles, proteins, bacteria, and microorganisms on membrane surfaces result often in membrane fouling that induces the severe flux loss and the increase of transmembrane pressure. Membrane fouling can be divided into reversible fouling and irreversible fouling. Reversible fouling is often attributed to the adsorption of foulants on membrane surface, and it can be recovered by physical or chemical membrane cleaning. While irreversible fouling is usually generated from the firm adhesion of foulants on membrane surface, and it is difficult to be removed even if a thorough membrane cleaning is done (Jonathan and Amy 2004). Therefore, the adhesion of foulants on membrane surface often brings a permanent deterioration of membrane performance. In such a case, the fouled membrane modules have to be replaced to continue a normal filtration operation.

In blood-contact membrane separation, for the blood incompatible membrane materials, the platelets in blood tend to accumulate and adhere onto membrane surface due to a biological immune reaction. As a result, thrombus formation may form and further result in some serious complications. Therefore, the blood-contact membranes such as hemodialysis membranes often need be modified to prevent the adhesion of platelets on membrane surface during blood filtration. In membrane science, the experiment of platelet adhesion on membrane surface is usually employed to evaluate the hemocompatibility of a blood-contact membrane. In biomedical application, the adhesion of microbes on membrane surface often leads to the bacterial infection of patients and the deterioration of membrane materials. Therefore, the control of microbial infection is a very important issue in biomedical membrane separation.

Adsorption onto Membrane Surfaces

Li-Ping Zhu

MOE Key Laboratory of Macromolecular Synthesis and Functionalization, Department of Polymer Science and Engineering, Zhejiang University, Hangzhou, Zhejiang, China

Adsorption onto membrane surface is the accumulation of gases, liquids, or solutes to form a thin film on membrane surface. In adsorption, the adsorbate is attracted to the surface of adsorbent, but does not enter its molecular spaces. As a surface phenomenon, adsorption is a consequence of surface energy. Adsorption is similar to adhesion and absorption, but there exist differences between them. Generally, compared to adhesion, adsorption is looser interaction between unlike substances. Adsorption is a surface-based process, while absorption involves the whole volume of the material. The exact bonding nature of adsorption depends on the details of the species involved, but the adsorption process is generally classified as physical adsorption and chemical adsorption. The physical adsorption is attributed to the non-covalent interaction such as van der

Waals force, electrostatic attraction, etc. The chemical adsorption features the formation of covalent bonding between adsorbate and adsorbent (Ferrari et al. 2010).

Commonly, in liquid filtration using a membrane, adsorptions onto membrane surface describe the accumulation and attachment of solutes in liquid on membrane surface driven by the minimization of interfacial energy. In water phase filtration, the adsorption of foulants such as proteins, colloids, microorganisms, etc., on membrane surfaces and membrane pore walls is often responsible to membrane fouling that induces a severe loss of membrane permeability and a change in membrane separation characteristics. The adsorption of foulants can be removed (desorption) by chemical or physical washing if the interaction between foulants and surfaces is weak. As a result, the membrane performances can be recovered partially or fully. In blood-contact membrane separation, protein adsorption on membrane surface often leads to the activation of complement system and blood coagulation and further results in serious complications of patients. Protein adsorption onto membrane surface is influenced by the surface characteristics such as wettability, surface chemistry, morphology, surface charge, etc. Therefore, surface modification of the blood-contact membranes to depress the adsorption of proteins on membrane surface has been a pursuit of membrane researchers (Rana and Matsuura 2010).

Advanced Oxidation Process (AOP) by Membrane Reactors

Kwang-Ho Choo

Department of Environmental Engineering,
Kyungpook National University, Daegu,
Republic of Korea

Advanced oxidation process (AOP) by membrane reactors is a synergistic hybrid of hydroxyl radical reaction and membrane filtration in a single reactor. Advanced oxidation process (AOP) is the uncontrolled, destructive action of hydroxyl radicals generated from ozone, H_2O_2 , ultraviolet radiation, Fenton reaction, electrolysis, sonolysis, and photocatalysis (e.g., TiO_2). AOP is most widely used for the decomposition of nonbiodegradable organic contaminants present in industrial and municipal wastewaters. It can be also applied for the degradation of micro-contaminants and taste-and-odor causing compounds in drinking water sources, such as pesticides, pharmaceuticals, endocrine disruptors, microcystins, geosmin, etc. Although micro-/ultrafiltration membranes are almost complete barriers for particulate matter and pathogens in water, they are limited in removing dissolved organic compounds. Thus, the coupling of membrane filtration with AOP in a reactor provides multifunctionalities and flexibilities for water and wastewater treatment systems.

Advanced oxidative membrane reactors are similar to biological membrane reactors (i.e., membrane bioreactors) in their concept except that biological oxidation is replaced by chemical oxidation. Due to the incompatibility of hydroxyl radicals and membrane materials (e.g., polymeric membranes), however, only a few examples of process configurations are developed and introduced, such as ozonated membrane reactor (Heng et al. 2007), photocatalytic membrane reactor (Choo et al. 2008), and electrochemically active filtration device (Vecitis et al. 2011). Figure 1 shows the schematics of such advanced oxidative membrane reactors. The ozone membrane reactor consists of ceramic tubular membranes made of alumina and zeolite which are chemically durable

Advanced Oxidation Process (AOP) by Membrane Reactors, Fig. 1 Examples of advanced oxidative membrane reactors: (a) ozone membrane reactor (Heng et al.

2007), (b) photocatalytic membrane reactor (Choo et al. 2008), and (c) electrochemically active filtration device (Vecitis et al. 2011)

while degrading a fraction of total organic carbon by ozone. The photocatalytic membrane reactor with suspended TiO_2 particles in aqueous phase enables polymeric membranes to be used because photocatalysis only occurs on the surface of TiO_2 photocatalysts where UV light bombards. The membrane permeability is enhanced with continuous photocatalysis of organic substances; otherwise they can foul the membrane severely. The fabrication and use of TiO_2 membranes for photocatalytic membrane reactors are of great interest, but UV light radiation is a major hurdle to be resolved. When a direct current of 2–3 V was applied onto multiwall carbon nanotubes loaded on a 5- μm polytetrafluoroethylene filter, substantial viral and bacterial removals are achieved by electrolysis in addition to filtration. Further process developments on AOP membrane reactors are expected with novel membrane materials and process designs.

Advanced Oxidation Processes (AOPs) and Membrane Operations

Kwang-Ho Choo
Department of Environmental Engineering,
Kyungpook National University, Daegu,
Republic of Korea

Advanced oxidation processes (AOPs) and membrane operations are composed of advanced oxidation followed by membrane filtration, where the former decomposes dissolved organic matter and the latter removes particulate matter. Advanced oxidation process (AOP) is the uncontrolled, destructive action of hydroxyl radicals generated from ozone, H_2O_2 , ultraviolet radiation, Fenton reaction, electrolysis, sonolysis, and photocatalysis (e.g., TiO_2). AOP is most widely used for the decomposition of nonbiodegradable organic contaminants present in industrial and municipal wastewaters. It can be also applied for the degradation of micro-contaminants and

Advanced Oxidation Processes (AOPs) and Membrane Operations, Fig. 1 Membrane flux enhancement with advanced oxidation pretreatments: (a)

ozonation plus ultrafiltration (Schlichter et al. 2004); (b) electrolysis plus microfiltration (Park et al. 2013)

taste- and odor-causing compounds in drinking water sources, such as pesticide, pharmaceuticals, endocrine disruptors, microcystins, geosmin, etc. This combined process can compensate the weak point of each process, but the oxidants left over should be quenched before their contact with polymeric membranes. This is because oxidants can deteriorate the membrane lifetime or integrity significantly due to the oxidation of the membrane. Polyamide membranes can be damaged even by the attack of chlorine and thereby, their physical properties and filtration performance are significantly impaired. Reducing agents, such as sodium sulfite, are mostly used for oxidant quenching.

A series of oxidation (e.g., ozonation) and micro-/ultrafiltration processes are designed and used for the treatment of drinking water which contains trace organic contaminants as well as metal species (e.g., Fe^{2+} , Mn^{2+}) (Hyung et al. 2000; Choo et al. 2005). Ozone can facilitate the oxidation of reduced forms of such metal ions and so help to precipitate out. The precipitates can be readily rejected by porous membranes. Electrolysis in combination with microfiltration is developed and tested for the treatment of municipal wastewater organic matter with simultaneous hydrogen production (Park et al. 2013). Electrochemical oxidation at a voltage of >2.3 V enables hydroxyl radicals to be generated while oxidizing

and ultimately mineralizing organic matter. Membrane operations after electrolysis achieve further removal of particles that can be hardly oxidized. A process configuration that consists of advanced oxidation (e.g., Fenton oxidation) followed by a membrane bioreactor is also an attractive option for the treatment of industrial wastewater containing recalcitrant organic chemicals (e.g., dyes) (Feng et al. 2010). This combination can be applied for the minimization of biological sludge generation while disintegrating excessive activated sludge (He and Wei 2010). To take advantage of prolonged oxidation, inorganic membranes (e.g., ZrO_2 and Al_2O_3 membranes), which are tolerant to strong oxidants, can be used instead of polymeric membranes. Particularly, advanced oxidation treatment prior to membrane filtration helps to reduce membrane fouling caused by organic substances (Fig. 1) (Park et al. 2013; Park 2002; Schlichter et al. 2004).

Cross-flow membrane bioreactor; Membrane bioreactor; Microfiltration membrane bioreactor; Submerged membrane bioreactor; Ultrafiltration membrane bioreactor

Introduction

Aerobic membrane bioreactors (MBRs) are one of the leading technologies to achieve sustainability in wastewater treatment through reuse, decentralization, and low energy consumption (Fane and Fane 2005; Fawehinmi et al. 2005). In aerobic MBRs, aerated activated sludge is coupled with membrane process to remove dissolved

contaminants (carbon and ammonia) and separate solids from the treated municipal or industrial wastewater. Carbon is removed by microorganisms that metabolize the carbon in the presence of dissolved oxygen for microbial growth and respiration (organic carbon reduced to carbon dioxide). Ammonia is removed through ammonia oxidation (nitrification). Nitrification is a microbially mitigated reduction process that occurs in an aquatic environment that contains moderate to high concentrations of ammonia and dissolved oxygen and low concentrations of organic carbon.

In submerged MBRs (Fig. 1), microporous (microfiltration (MF) or ultrafiltration (UF) (► [Ultrafiltration](#))) membranes are immersed in a bioreactor, and water is filtered (► [Permeate](#)) through the membranes using vacuum; suspended solids are retained in the system; and high levels of treatment (including nutrient removal) can be achieved (Judd 2006). The MBR replaces the two-stage conventional activated sludge process (biotreatment and clarification) with a single, integrated process (► [Wastewater Treatment in Membrane Bioreactors](#)). The advantages of MBRs over conventional treatment have been thoroughly reviewed (Stephenson et al. 2000), and they include product consistency, reduced footprint, reduced sludge production, and nearly complete suspended solid separation from the effluent. Additionally, MBR effluent may be suitable for use as irrigation water, as process water, or as a pretreatment for potable reuse applications (Membrane Bioreactors for Reuse; Potable Water Production) (Lawrence et al. 2002).

However, the establishment of membrane bioreactor technology (Anaerobic Membrane Bioreactor; Attached Growth Membrane Bioreactor; Membrane Bioreactors (MBR) for Plants; ► [Submerged Membrane Bioreactor](#)) has been slower than expected because decision-makers view MBRs as high risk and costly compared to conventional technology (Judd 2006). To date, MBRs have been used to treat municipal and industrial wastewater where water reuse is desired, a small footprint is required, or stringent discharge standards exist (Kang et al. 2007; Yang et al. 2006).

Aerobic Membrane Bioreactor,

Fig. 1 Schematic representation of a submerged aerobic MBR system

Current Limitations

One of the major limitations to widespread application of MBR technologies is to control membrane fouling with modest energy and chemical input (► [Irreversible Fouling](#); ► [Reversible Fouling](#)) (Le-Clech et al. 2006). Membrane fouling (Biological Fouling; Cake Layer; ► [Inorganic Scaling](#)) has been investigated from various perspectives, including the causes, characteristics, and mechanisms of fouling and methods, to prevent or reduce membrane fouling (Achilli et al. 2011; Judd 2005; Le-Clech et al. 2006; Meng et al. 2009; Wang and Wu 2009). Fouling markedly affects membrane cleaning (Membrane cleaning, 369690) and replacement intervals, system productivity, and membrane integrity; all of which are factors that affect energy requirements and costs (Judd 2006; Le-Clech et al. 2006).

Operation

In order to operate conventional MBRs at constant flux, physical membrane-cleaning techniques are utilized; they include air scouring, backwashing, relaxation, or a combination of the three, depending on the membrane configuration (hollow fibers, flat sheet, or tubular). Air scouring is required for submerged MBR configurations to gas lift fresh sludge through the membrane bundle or cassette and to scour solids from the membrane surface. During backwashing, permeate is

pumped in the opposite direction through the membrane, effectively removing most of the reversible fouling (► [Backwashing](#)). The efficiency of backwashing has been studied in detail, and the key parameters have been found to be frequency, duration, and intensity (► [Backwashing Frequency](#)) (Bouhabila et al. 2001; Psoch and Schiewer 2005, 2006). During membrane relaxation, permeate suction is stopped, and the back transport of foulants is naturally enhanced as reversibly attached foulants diffuse away from the membrane surface.

Membrane backwashing and relaxation are regularly used for tubular and hollow fiber membranes to control fouling (Bouhabila et al. 2001; Hong et al. 2002; Psoch and Schiewer 2005, 2006; Smith et al. 2005). This is not the case for flat-sheet membranes that cannot be backwashed due to their inability to withstand pressure in the opposite direction of the operating flow; for this reason, relaxation is used to control the fouling of these membranes (Le-Clech et al. 2006). Regardless of the membrane configuration, chemicals must be used at regular intervals to enhance physical cleaning (Le-Clech et al. 2005).

Affinity Membranes

Francesca Militano^{1,2} and Lidietta Giorno¹

¹Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

²Univeristy of Calabria, Rende, Italy

Introduction

Affinity separation methods rely on a “molecular recognition” phenomenon between species. A molecule, known as the ligand, is permanently bounded onto an inert matrix and specifically recognizes the molecule of interest, known as the ligate, that can be separated. The ligand can be a naturally occurring molecule, an engineered macromolecule, or a synthetic molecule linked to the matrix by covalent coupling. The ligand-ligate interaction is selective and reversible, enabling the separation and fine purification of biological substances such as proteins, peptides, and nucleic acids on the basis of its individual chemical structure or biological function (Wilson and Poole 2009).

Among the separation techniques based on the affinity method, affinity chromatography is the most widely used. Due to the limitation associated to the traditional affinity chromatography with porous bead-packed columns (i.e., limited flow rate by pore diffusion), the membrane-based separation technique is gaining an increasing

importance. Indeed, affinity membranes combine the specificity of affinity adsorption (of the common affinity resins) with the high productivity associated with filtration membranes. They provide low pressure separation systems without diffusional limitation, as the mass transfer is mainly governed by convection (Klein 2000). Microporous membranes, both in flat sheet and hollow fiber configuration, coupled with biological or biomimetic ligands have been used as affinity membrane chromatography supports (Zou et al. 2001).

Affinity Membrane Preparation

The realization of affinity membranes usually involves three steps: (1) preparation of the basic membrane, (2) activation (functionalization) of the basic membrane, and (3) coupling of affinity ligands to the activated membrane.

Membrane Material

The membrane materials should possess some characteristics: (i) hydrophilicity to minimize the nonspecific adsorption of bioactive species, (ii) chemical and physical stability under harsh conditions used during ligand coupling and ligand-ligate complex formation, (iii) large surface area relative to membrane volume, (iv) biocompatibility when the membrane is used for blood treatment, and (v) presence of functional groups required for the coupling of the ligands (such as $-\text{OH}$, $-\text{NH}$, $-\text{SH}$, $-\text{COOH}$).

The commercially available materials used for affinity membrane preparation include organic (natural or synthetic polymer), inorganic, and composite materials.

Among the first materials used for affinity membrane preparation, cellulose and its derivatives (regenerated cellulose, cellulose acetate) were the most common. These present a hydrophilic and biocompatible surface, low nonspecific adsorption, and abundant reactive hydroxyl groups that can be easily activated by different strategies for the ligand coupling. To improve the

density of functional groups and increase the mechanical strength, composite cellulose membranes have been also prepared by chemical grafting with acrylic polymers.

Another suitable membrane material is polyvinyl alcohol, thanks to its hydrophilicity and biocompatibility. Like cellulose, it contains hydroxyl groups that can be easily activated.

Polyamide and nylon have been also used for the preparation of affinity membranes, thanks to their good mechanical and chemical stability. Nylon membranes have a low concentration of amino groups to serve as functional groups for ligand coupling. Also, due to the hydrophobic surface, the membrane presents a high nonspecific adsorption of biomolecules during affinity separation process. Therefore, the hydrolysis of the membrane is generally performed to increase the density of reactive groups and to prevent electrostatic interaction with proteins. To overcome these problems, composite nylon membranes have been also prepared.

Other materials that have been used for affinity membranes are poly(methyl methacrylate), polysulfone and its derivative, polycaprolactam, polyvinylidene difluoride, poly(ether-urethane-urea), and inorganic materials such as glass.

Membrane Activation and Ligand Coupling

If the basic membrane does not possess the functional groups for ligand coupling, it can be activated.

In Table 1 are reported the commonly used activation agents with respect to the functional groups present on the basic membrane.

The coupling of the ligand directly on the activated membranes may result in low binding specificity due to the low steric availability (in particular when the ligand is a small molecule). This problem is generally overcome by the introduction of a spacer molecule to the membrane prior to attaching the ligand, improving the ligand accessibility for the molecule to be separated. Spacer arms are bifunctional molecules able to react with both the membrane and ligand.

Affinity Membranes, Table 1 Some commonly used activation agents for affinity membrane preparation

Activation agent	Structure	Functional groups of the basic membrane
Cyanogen bromide	$\text{N}\equiv\text{C}-\text{Br}$	-OH
Carbonyldiimidazole		-OH, -NH ₂
2-Amino-4,6-trichloro-s-triazine		-OH
Glutaraldehyde		-OH, -SH, -NH ₂
Divinyl sulfone		-OH, -SH
Epichlorohydrin		-OH, NH ₂

Affinity Ligands

Affinity ligands can be classified into biospecific and pseudo-biospecific ligands (Klein 1991). Biospecific ligands are biomolecules such as antibodies, antigens, and proteins A and G that show specificity for only one complementary biomolecule.

Because of their selectivity, biomolecules have been the most widely used affinity ligands on affinity membrane separation technology. One of the most common applications is the use of immobilized monoclonal antibodies for immunoaffinity separation. Another important example is membranes with covalently coupled protein A or protein G for immunoglobulin purification from plasma, serum, or cell culture supernatants.

Although the biospecific ligands possess high specificity for proteins, they have some limitation for large-scale application due to their poor stability and high price.

The alternative approach to biospecific ligands involves the use of pseudo-biospecific ligands. These are usually molecules with higher chemical and physical stability than biomolecules. Pseudo-biospecific ligands can be distinguished by biological (amino acids, specially histidine, lysine, tryptophan) or non-biological molecules (dyes, chelated metal ions).

The working principle of pseudo-biospecific ligands relies on the complementarity of structural features of ligand and ligate rather than on a biological function. Immobilized dyes have been found to act as affinity ligands for a wide variety of biological molecules. For example,

Affinity Membranes, Table 2 Some examples of the use of affinity membranes for isolation and purification of biomolecules

Membrane	Ligand	Ligate	Application
Cellulose and regenerated cellulose	Cibacron Blue F3GA	Alkaline phosphatase	Purification
	Protein A/G	IgG	Purification
	Histidine	Endotoxin	Removal of endotoxin
Poly(ethylene-co-vinyl alcohol)	Histidine	IgG	Purification
Nylon	Cibacron Blue	Glucose-6-phosphate dehydrogenase	Purification
	Protein G	IgG	Purification
	Histidine	Endotoxin	Removal of endotoxin
Polyvinylidene difluoride (PVDF)	Protein A	IgG	Purification
Polysulfone (PS)	Trypsin	Trypsin inhibitor	Purification
	Iminodiacetic acid (IDA)	Histidine/tryptophan	Purification
Glass	IDA-Cu ²⁺	Lysozyme, cytochrome c, ribonuclease A	Purification

triazine-linked dyes have been used to mimic coenzymes that bind a number of dehydrogenases, hexokinases, and alkaline phosphatases; the reactive triazine groups can be linked to any matrix containing hydroxyl groups by mixing the two together. Cibacron Blue F3GA (a textile dye) has been employed as ligand in affinity membranes for the purification of over 80 enzymes and proteins.

Another important example of pseudo-biospecific affinity ligands is chelated metal ions used for the purification of histidine-tagged fusion proteins.

Molecular Imprinted Membranes

A different approach for the preparation of affinity membranes is the use of molecularly imprinted polymeric materials. These are produced by entrapping a template molecule (the molecule to be separated) in a polymer matrix during polymerization and subsequent extraction. In this way, binding sites are introduced in the polymer that

are complementary in shape and functionality to the target molecule.

Applications of Affinity Membranes

Affinity membranes are used for several different applications such as purification of biomolecules, removal of unwanted substances from biological fluids, and also small-scale analytical separations.

The most common application is the separation and purification of biomolecules and especially proteins for large-scale production.

In Table 2 are reported some typical examples of their use for the separation and purification of biomolecules.

Affinity Membranes for Adsorptive Separation Process

Shing-Yi Suen

Department of Chemical Engineering, National Chung Hsing University, Taichung, Taiwan

Affinity membrane (also called *adsorptive membrane*, *membrane adsorber*, or *membrane chromatography*) is a design using membrane for adsorptive separation. The traditional shape for adsorbents is particle. In batch process, particulate adsorbents need to be suspended uniformly in liquid bath by agitation for good contact with adsorbates. After adsorption, centrifugation/filtration/precipitation is required to separate solid particles from the liquid. On the other hand, particulate adsorbents are commonly packed in a column/vessel (so-called *chromatography* or *packed bed*) for flow operation, where various operational conditions (fixed bed, moving bed, fluidized bed, etc.) could be applied. However, pressure drop and intraparticle diffusion limitations usually restrict the separation effectiveness of large-scale chromatographic system. An advantageous alternative for adsorptive separation is to adopt porous membrane with suitable functionality (adsorptive membrane), which has exhibited better mass transfer effects by convective transport of solutes and minimal thickness to allow operation at low pressure (Roper and Lightfoot 1995; Charcosset 1998; Zou et al. 2001; Ghosh 2002; Suen et al. 2003).

Adsorptive membranes are mainly applied in separation of biomolecules (proteins, DNA, endotoxins, etc.). Their application has been extended to the removal of toxic contaminants from wastewater (Wu et al. 2008). The interactions between adsorbates and adsorptive membranes are identical to those using particulate adsorbents. They could be categorized into four modes: affinity, ion exchange, hydrophobic interaction, and reverse phase (Roper and Lightfoot 1995; Charcosset 1998). Affinity mode provides strong specific binding, such as biospecific, immunoaffinity, dye affinity, immobilized metal ion affinity, and pseudo affinity. Ion exchange adsorption, including weak and strong, cation and anion exchange, is based on electrostatic interaction so that fast binding and high recovery are easily attained to increase its popularity in commercial products. The last two modes are both induced by van der Waals force and hydrophobic interaction, with a difference that the strength of reverse phase mode is larger. The applications of these two modes are limited due to the probable inactivation of biomolecules.

Several methods could be employed to prepare the adsorptive membranes: (1) polymerization of monomers containing special functional groups (or *ligands*), followed by dissolving of polymer and casting it into a film; (2) introduction of functional groups into a polymer in solution and casting it into a film; (3) immobilization of functional groups onto a preformed membrane; and (4) blending of particulate adsorbents and polymer solution together and casting it into a film (so-called *mixed matrix membrane*) (Avramescu et al. 2003; Saufi and Fee 2009).

Adsorptive membrane system can be operated using commercially available geometries such as flat sheet, tubular/hollow fiber, spiral wound, etc. (Roper and Lightfoot 1995; Zou et al. 2001; Suen et al. 2003). Figure 1 depicts the flow process of adsorptive membrane (i.e., membrane chromatographic system). Similar to a conventional chromatographic system with particulate adsorbents, a cycle of operation consists of

Affinity Membranes for Adsorptive

Separation Process,

 of flow process for
 adsorptive membrane

loading (adsorption), washing, elution (desorption), and/or regeneration. To achieve a larger-scale adsorptive capacity, it is simple and convenient to stack flat sheet membranes in series or wind a larger sheet around a cylindrical core.

Affinity Membranes for Purification of Enzymes

Renbi Bai and Xiaoying Zhu
 Department of Civil and Environmental
 Engineering, National University of Singapore,
 Faculty of Engineering, Singapore, Singapore

Enzymes and Their Purification

Enzymes are large biological molecules that catalyze chemical interconversions. Most enzymes are proteins and they are highly selective catalysts. Since enzymes are selective for their substrates and speed up only specific reactions from among many possibilities, the types of enzymes determine the pathways and therefore affect the products of reactions. Hence, there is always the need for enzymes of different types to be separated and purified.

Affinity Membranes

Conventional membranes generally act like a sieve for separation, blocking substances larger than the membrane pores and passing substances smaller than the membrane pores. However, affinity membranes operate not only on the sieving mechanism but more importantly have

selective binding capabilities, provided by various binding sites on the external and internal surfaces of the membranes. Thus, affinity membranes can separate and purify substances with the combined advantages of high selectivity due to the specific binding sites and the high productivity of conventional filtration membranes.

Many affinity membranes were developed by postmodifications of existing microporous ultrafiltration and microfiltration membranes. Due to the different membrane materials, various modification approaches may have to be used to provide the specific binding sites on the membranes. For example, polymeric membrane materials with functional end-groups can directly react with reactive ligands. On the other hand, inert membrane materials, such as aliphatic hydrocarbons without active side chains or end-groups, are usually modified by radiation chemistry to incur their reactivity for ligand immobilization. Premodification of membrane materials may be another route to prepare affinity membrane. Functional monomers with binding sites were polymerized to have functionalized polymers that are subsequently used to fabricate affinity membranes.

The applications of affinity membranes are similar to those of affinity chromatography developed with the bead columns, but affinity membranes have the advantage of shorter process time, increased separation efficiency at low pressures, and greater productivity.

Purification of Enzymes with Affinity Membranes

One of the most important applications of affinity membrane is in purification of proteins or enzymes. The affinity membranes will trap or adsorb specific proteins or enzymes during the filtration of their solutions. The trapped proteins or enzymes are subsequently eluted from the membranes and concentrated to get the purified products. In general, there are three types of interactions between the affinity membranes and the enzymes. The first type of interaction is electrostatic interaction. Anions or cations are covalently immobilized onto the membranes to trap

positively charged or negatively charged enzymes, respectively. For example, porous nylon membranes were modified with poly(2-(methacryloyloxy)ethyl succinate) brushes to purify positively charged lysozyme from chicken egg white (Jain et al. 2010). Negatively charged sulfonyl matrices acting like ion exchangers were prepared on cellulose membranes to purify crude cationic urokinase (plasminogen-activating enzyme) from human urine at pH 4.5 (Hou and Zaniewski 1990). These affinity membranes can trap all positively charged enzymes or negatively charged enzymes at the same time. In other words, if one needs to have a particular type of enzymes, the concentrated enzymes from the membrane need further purification.

The second type of affinity membranes can provide more specific enzyme purification. These affinity membranes can bind enzymes through the interaction between a Lewis acid (electron pair donor), such as a chelated metal ion and an electron acceptor group, such as histidine or tryptophan residues on His-tagged recombinant proteins. This purification mechanism is the same as immobilized metal affinity chromatography (IMAC) which is a commercial protein purification method targeting His-tagged recombinant proteins. For example, poly(2-(methacryloyloxy)ethyl succinate) brushes of a porous nylon membrane were further functionalized with nitrilotriacetate (NTA)-Ni 2^{+} to bind His-tagged ubiquitin (Jain et al. 2010). These affinity membranes usually can rapidly get highly purified His-tagged proteins from cell extracts.

The third type of affinity membranes is using immobilized ligands to bind complementary enzymes. For example, heparin was covalently linked to a commercial membrane to bind antithrombin III which was recovered with 91 % purity and 97 % yield (Lutkemeyer et al. 1993).

Affinity Separation and Crystallization of F_c Fragments

Nilay Bereli, Handan Yavuz and Adil Denizli
Department of Chemistry, Biochemistry Division,
Hacettepe University, Ankara, Turkey

Immunoglobulins are used by the immune system present in serum and tissue fluids to identify and neutralize foreign targets. Immunoglobulins are “Y”-shaped molecules comprised of two identical light chains (L) and two identical heavy chains (H) linked via disulfide covalent forces and via non-covalent interactions. Each chain has constant (C_L and C_H) and variable (V_L and V_H) domains (Holt et al. 2003). These form two antigen-binding fragments (F_{ab}) that specifically recognize and bind to antigen molecule and a constant fragment (F_c) which is responsible for

the effector function and biodistribution of the antibody (Beale 1987). Proteolytic digestion provides important information to determine an antibody molecule’s structure and function. Antibody molecules can be cleaved into fragments and each of these fragments has a distinct activity. A number of enzymes like papain, pepsin, ficin, bromelain, and elastase can be used for this purpose, papain being the most frequently used (Luo et al. 2002). Because of their smaller size as functional components of the whole molecule, antibody fragments offer several advantages over intact antibodies for use in certain immunochemical techniques and experimental applications. For this purpose, researchers have attempted to use smaller, more stable counterparts of antibodies and have also been searching for alternative ways to obtain antibody-like receptors (Haupt et al. 1998). Thus, bioengineered antibody fragments that are smaller than antibodies and have the ability to bind antigen bivalently have been promoted by the researchers (Cortese 1995). IgG molecule can be digested with papain for gaining F_{ab} and F_c fragments.

For the separation of F_{ab} and F_c fragments, HiTrap_r Protein A column can be used and collected the fragments by the fraction unit of the fast protein liquid chromatography (FPLC) system (Ertürk et al. 2011; Bereli et al. 2013; Aslıyüce et al. 2013). As shown in Fig. 1, a successful separation was observed and F_{ab} and F_c fragments

Affinity Separation and Crystallization of F_c Fragments, Fig. 1 FPLC chromatogram of IgG after digestion with papain (Ertürk et al. 2011)

Affinity Separation and Crystallization of F_c Fragments, Table 1 Chromatographic separation data

Fragment	t _R	N	K'	α	R _s
F _{ab}	3.06	52.39	1.19	6.14	-
F _c	11.16	1089.60	7.31	-	4.70

were separately collected. The retention times of the fragments were achieved at 3.06 and 11.64 min, respectively. The calculated chromatographic parameters such as t_R, N, k', α , and R_s values are summarized and given in Table 1. R_s value was calculated as 4.70 for F_c fragment. Because the R_s value should be higher than 1.0 for a good resolution of two peaks in such a chromatography system, the results for the resolution of F_{ab} fragment/F_c fragment can be accepted as good resolution values.

Aged Carbon Membrane

Miki Yoshimune

Research Institute for Chemical Process Technology, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan

If the use of high-performance carbon membranes in gas separations is to be commercialized, the aging characteristics of such membranes will become important. Little work has been done on studying this aspect of carbon membranes, but some researchers have pointed out that there are significant problems related to the performance stability of carbon membranes (Jones and Koros 1995a; Lagorsse et al. 2004, 2005; Saufi and Ismail 2004). Although they are chemically and thermally resistant, carbon membranes generally suffer deterioration in performance upon exposure to substances that become strongly adsorbed, such as water vapor or oxygen. As carbon membranes have a sharp pore-size distribution with a critical size ranging from 0.3 to 0.7 nm, small changes in the effective size of the pore structures can markedly affect their permeability toward adsorbing gas molecules. In addition, constrictions in the pore system can occur as a result of chemisorption of oxygen or by strong adsorption of species having very low diffusivity because of their organophilic nature. Such species will block the pores in the membrane and attenuate the permeation of other species.

In a study of the effects of air oxidation and humidity at room temperature on the aging of carbon membranes, Menendez and Fuertes (2001) found the membrane stored in dry or humid air underwent a rapid loss of permeability, whereas membranes stored under propene or nitrogen were protected from damage. The researchers suggested that chemisorption of oxygen rather than physisorption of water is principally responsible for the loss of permeability that occurs when a fresh carbon membrane is exposed to air.

Jones and Koros (1994) found that carbon membranes are highly vulnerable to adverse effects of exposure to organic contaminants, even at concentrations as low as 0.1 ppm. Attempts to regenerate membranes after exposure to hydrocarbons by high-temperature (363 K) treatment in a vacuum were unsuccessful. Jones and Koros (1995a) also studied the effects of humidity on the O₂/N₂ selectivity and permeability of a carbon membrane by using feeds with relative humidities of 23–85 %. Some losses in performance occurred at all humidity levels, but this problem could be alleviated by rendering the surface of the membranes hydrophobic by coating them with thin layers of Teflon AF1600 or AF2400 (Jones and Koros 1995b). The resulting composite carbon membranes were significantly protected from the adverse effects of humidity.

Lagorsse et al. (2008) made a thorough investigation on the effects of exposure to air and humidity on the performance of commercialized carbon hollow fiber membranes, supplied by Carbon Membranes Ltd. (Israel). The production of these membranes involved pyrolysis followed by chemical vapor deposition and an activation step (Lagorsse et al. 2004). The researchers found that the membrane underwent a loss of permeability with time when exposed to pure oxygen or to air; however, the performance of the membrane ultimately stabilized after prolonged exposure. Attempts to regenerate the membranes by exposure to flowing nitrogen at 343 K or by treatment with propene and propyne as cleaning agents resulted in no significant recovery of permeability. However, no deterioration in permeability of these membranes was observed when they were stored under nitrogen. The researchers therefore concluded that aging of carbon membranes is caused exclusively by chemisorption of oxygen from air. On the other hand, humidity adversely affects the performance of membranes in multicomponent separation processes because water is strongly adsorbed, but diffuses relatively easily through the membranes. Heating under an atmosphere of hydrogen at 893 K to remove surface oxygen groups had some effect on stable surfaces protected from chemisorption of

oxygen. This treatment can be used to restore the permeation properties to those of fresh membranes.

These studies demonstrated that the effects of aging are more pronounced when membranes are stored under a high-humidity atmosphere and are exposed to air. The chemisorption of oxygen leads to the formation of C–O surface groups, thereby creating a more hydrophilic interface that favors increased adsorption of water. Adsorbed species can reduce the pore size of the carbon over time, leading to decreases in the permeability and selectivity of the membrane. Therefore, studies on the stability of carbon membranes will be an important aspect on research on such membranes in the future.

Air Bubbling in Membrane Distillation

Chunrui Wu

State Key Laboratory of Hollow Fiber Membrane Materials and Membrane Processes, Institute of Biological and Chemical Engineering, Tianjin Polytechnic University, Tianjin, China

Air bubbling is a common method that is used in membrane separation process to alleviate membrane fouling and improve flux. It also is a kind of membrane cleaning method. Till now, gas-liquid two phase flow has been well studied and widely used in microfiltration, ultrafiltration (Cabassud et al. 1997), membrane bioreactor (Psoch and Schiewer 2005), and other traditional membrane separation technologies.

Based on the above advantages of air bubbling, it has been introduced into membrane distillation (MD) process to alleviate membrane fouling and improve the heat and mass transfer efficiency. Researchers have introduced air bubbling into MD process and developed several new kinds of MD process.

The first application of air bubbling in MD process was firstly reported in 2008 (Ding et al. 2008) to concentrate the extract of traditional Chinese medicine (TCM). Air bubbling was used

in direct contact membrane distillation (DCMD) and the flow sheet is shown in Fig. 1.

The TCM extract was heated to 43–62 °C and pumped to the module; another pump was used to circulate the permeate water (maintained at 25 °C) at the permeate side of the membrane module. The velocity of the feed and permeate flow in the membrane module ranged from 0.07 to 0.13 m/s. To mitigate membrane fouling, a fan was used to create gas bubbling at the feed side of the membrane module. This fan was also utilized to generate gas sparging at the permeate side for gas backwashing of the membrane. The concentration ratio (CR) was defined as the ratio of the volume of initial extract to the volume of concentrated extract to indicate the concentrating performance of the experiments.

The result showed that a sharp flux decline right after the air was introduced into the feed circulation, and the flux remained at much lower level when air was continuously injected. The explanation authors gave was that the bubbles occupied part of the liquid-contacting area in the membrane, thus reducing the effective membrane area, and when gas entered the membrane pores, this reduced the partial pressure of water vapor within the pores, thus reducing the driving force. To reduce these effects, intermittent gas sparging at the feed side at intervals of 20 min and lasting only 2 min was applied.

The effect of gas bubbling on the DCMD performance was shown in Fig. 2. It could be seen that flux declined rapidly in the beginning of the

Fig. 2 Performance of DCMD using gas bubbling on the feed side

Air Bubbling in Membrane Distillation,

Fig. 3 Theoretic diagram of ABMD process

experiment and then slowly as a result of the very low-flux level at this time. The introduction of gas bubbling at the feed side resulted in a higher flux in the beginning of the experiment and a much slower flux decline. Very similar trends were observed with gas bubbling at 1 and 2 L/min which meant that increasing the gas flow rate did not result in further process enhancement.

A novel air-bubbling vacuum membrane distillation (AVMD) process was constructed in 2011 (Wu et al. 2011) to investigate the enhancement effect of air bubbling on traditional VMD

process. Compressed air was pressed into the lumen side of the hollow fiber membranes together with the hot feed solution just at the inlet of membrane module to form gas-liquid two phase flow, as shown in Fig. 3.

The results showed that the permeate flux increased with the air flow rate and/or feed temperature increasing. For the VMD process, the permeate flux was $22 \text{ kg/(m}^2\text{h)}$ when tested at 75°C with a feed flow rate of 120 L/h and a vacuum pressure of 0.0085 MPa . While, the flux of AVMD process could reach $40 \text{ kg/(m}^2\text{h)}$

Air Bubbling in Membrane Distillation, Fig. 4

Effect of feed gas flow rate on the performance of AVMD process

Air Bubbling in Membrane Distillation, Fig. 5

(a) Air inlet connected to the membrane module; (b) Air nozzle

when gas was introduced into feed solution at the rate of 60 L/h, as shown in Fig. 4. For the two processes, flux both declined gradually as the feed concentration increased from 3.5 to 300 g/L, but it was much slower for AVMD process. SEM pictures showed that membranes used in AVMD process had lighter fouling than that in VMD process.

For elevated salt concentrations in the feed steam, gas bubbling was introduced into direct contact membrane distillation (DCMD) in 2013 (Chen et al. 2013) to examine its effect on the MD performance. In the paper, to characterize the performance improvement achieved by gas bubbling, the flux enhancement ratio Φ is defined:

$$\Phi = \frac{J_{\text{gas}}}{J_{\text{nogas}}}$$

where J_{gas} and J_{nogas} are the permeate fluxes in the DCMD process with and without bubbling, respectively.

Gas bubbling is supplied by an air pump. The air inlet at the feed side entrance of the membrane module and the air nozzle for dispersing the air are shown in Fig. 5.

The results showed that the introduction of gas bubbling could effectively enhance MD flux, and the flux enhancement ratio could reach 1.72 at an optimized gas flow rate. When the condition was either a high feed operating temperature, low feed

Air Bubbling in Membrane Distillation, Fig. 6 Effect of gas flow rate on Φ in laminar and turbulent flows

and permeate Reynolds numbers, or a module with 45° inclined orientation, shorter fiber length, or lower packing density, a higher flux enhancement ratio could be achieved. Because air bubbling could enhance the turbulence of feed solution, temperature polarization was effectively reduced. However it was not that the bigger the gas flow rate, the higher the enhancement ratio. It was observed that beyond an optimal gas flow rate, the enhancement ratio fell, possibly due to excessive flow bypassing.

The effect of gas flow rate on Φ in laminar and turbulent flows was shown in Fig. 6. In the figure, it was observed that these two Φ curves had a similar trend. At first, Φ increased with increasing gas flow rate in the range of $0 \leq Q_g \leq 0.2 \text{ L min}^{-1}$ for the laminar flow and $0 \leq Q_g \leq 0.5 \text{ L min}^{-1}$ for the turbulent flow, while Φ decreased when gas rate was higher. Furthermore, the Φ value of the laminar condition was much higher than that of the turbulent flow when other conditions were the same.

In 2009, air bubbling was used in a hybrid process combining membrane distillation in a submerged membrane bioreactor (MDBR) to mitigate severe fouling and flux decline (Phattaranawik et al. 2009). The result showed that adding two inlets for air sparging at 2.5 L/min each near the potting at the center of the membrane bundle induced more turbulence at the membrane surface. Over 15 days, fluxes were

still relatively stable with an average value of $5.16 \text{ L/(m}^2\text{h)}$.

To sum up, air bubbling was an effective method in membrane distillation to enhance the performance of MD process. Due to the role of increasing turbulence of feed solution, air bubbling could promote the agitation and mix of feed solution to decrease the temperature and concentration polarization effect. In addition, the enhancing surface shear rate increases the remove of foulant from membrane surface at the feed side to inhibit the influence of membrane fouling.

Air Dehydration by Membrane Technology

Wei Liu

Energy and Environmental Technology
Directorate, Pacific Northwest National
Laboratory, Richland, WA, USA

Synonym

Membrane air dehydration

Air dehydration refers to removal of moisture from humid air and is also termed as air dehumidification and air drying. Due to the ubiquitous presence of moisture in air, air dehydration represents one of the largest membrane applications. Air dehydration through a membrane is essentially a vapor-phase separation process (Fig. 1), which can be carried out in two ways. In one way, moisture in the feed air diffuses across the membrane and is swept out of the membrane unit with a sweep gas stream (Fig. 1a). In another way, the permeated moisture is pulled away from the membrane unit by vacuum (Fig. 1b).

In the sweeping process, degree of air dehumidification will be limited by moisture content in the sweep gas and operation pressures, as explained by the following equations:

$$\Delta p = x_F \cdot p_F - x_S \cdot p_P > 0$$

$$x_F > \frac{x_P \cdot p_P}{p_F}$$

Low molar fraction of moisture in sweep gas (x_P), low permeate pressure (p_P), and high

feed pressure (p_F) favor for deep dehumidification, i.e., allowing low moisture content in feed air (x_F).

If no sweep gas is used, the permeate pressure has to be decreased by vacuum to obtain a positive partial pressure gradient of water vapor across the membrane:

$$p_P < x_F \cdot p_F$$

Membrane dehydration is commonly used in industries for removal of moisture from pressurized air. In these applications, ambient air at atmospheric pressure is often used as sweep gas. Though moisture content (such as molar fraction) in the sweep air may be the same as in the process air, a significant partial pressure gradient of water vapor can be managed due to high pressures in the process air. For example, hollow fiber membranes are used for drying of the air pressurized to about 10 bar (Morgan et al. 1996). Air-sweep dehumidification can also be found in some laboratory membrane devices, such as Nafion membrane tubes for moisture exchange (Ye and LeVan 2003).

When humid air is at low or atmospheric pressures, using ambient air as a sweep stream is no longer practical, and pulling vacuum in the permeate side becomes necessary. In this case, several other pieces of equipment in addition to the membrane separator are required to make an integrated dehumidification system (Fig. 2). Such a membrane dehumidifier has been recently proposed and is still under development (Xing et al. 2013). An array of membrane units can be assembled together that the permeate sides of all the membrane units are connected to one common vacuum line. The vacuum is generated by the use

Air Dehydration by Membrane Technology, Fig. 1 Removal of moisture from humid air through a membrane

Air Dehydration by Membrane Technology, Fig. 2 Process flow diagram of a membrane dehumidification system

of a vacuum pump or gas compressor. The permeated moisture is compressed to a pressure above water dew point at environmental temperature so that water vapor is condensed into liquid-phase water by rejecting heat of condensation into environment. The condensed water is collected in a reservoir. Water in the reservoir may be discharged using a liquid pump, while residual air – noncondensable gas – is discharged into environment using a secondary vacuum pump.

Air Enrichment, by Polymeric Magnetic Membranes

Anna Strzelewicz

Faculty of Chemistry, Silesian University of Technology, Gliwice, Poland

The idea of using magnetic membranes for enrichment of air by oxygen is based on the observation that oxygen and nitrogen have quite different magnetic properties, i.e., oxygen is paramagnetic whereas nitrogen diamagnetic. The oxygen molecule is paramagnetic with a magnetic moment of $\mu_{O_2} = 2.73 \times 10^{-23} JT^{-1}$. Magnetic susceptibility of nitrogen is equal to $\chi = -150.8 \times 10^{-6} mol^{-1} = -2.5 \times 10^{-28} molecule^{-1}$ which corresponds only to $\mu = 2.5 \times 10^{-28} JT^{-1}$ in a magnetic field of 1 T, a value five orders of magnitude smaller than the O_2 magnetic moment (Morrish 1965; Borys et al. 2011).

Magnetic membranes are polymeric membranes (ethyl cellulose (EC) or poly(2,6-dimethyl-1,4-phenylene oxide) (PPO)) with dispersed

Air Enrichment, by Polymeric Magnetic Membranes,

Fig. 1 Scheme of the experimental setup

magnetic powder (ferrite, praseodymium, and neodymium). The membranes are made by casting of appropriate polymer solution with dispersed magnetic powder in an external magnetic field of a specially designed coil (stable magnetic field with range of induction 0–40 mT). Removed from Petri dish membranes are dried in 40 °C for at least 2 days and then are stored in an exsiccator under the vacuum conditions ($p = 3$ mmHg). Collection of permeation quantities both for individual gases (O_2 , N_2) and for their mixture (air 21 % O_2 /79 % N_2) is measured in experimental setup (Fig. 1).

The measurements are carried out in room temperature for membranes with dispersed magnetic powder before and after magnetization in a field magnet with magnetic induction about 2.5 T. The setup furnished with a gas chromatograph allows to measure the oxygen and the nitrogen concentration in permeate. The main part of the experimental setup is diffusive chamber, where the membrane is put in the form of disk. The setup is used for a low-pressure (from 0.1 to 1.0 MPa) analysis of gas permeation. Transport coefficients can be calculated using flow rate data and percentage of air enrichment. The flow rate of the permeate can be recorded using a flowmeter.

Integration of flux with respect to time allows to sketch a downstream permeation curve. Typical plot of $Q^a(l,t)$ versus time is presented in the Fig. 2.

Time-lag method and D1-D8 system allow to get some insight into the nature of the considered transport process. In papers (Strzelewicz and Grzywna 2007, 2008; Rybak et al. 2009a, b, 2012; Grzywna et al. 2010) a concept of magnetic membranes for air enrichment is explained. The authors observed an increase in the oxygen flux with respect to the nitrogen flux and the enrichment in the oxygen content of the permeate up to 55.6 % for ethyl cellulose magnetic membranes. Further permeation measurements done in polyphenylene oxide (PPO) magnetic membranes provided higher enrichments, up to 61.9 % (Table 1).

The transport of the molecules through the magnetic membranes can be modeled by a diffusion with a position-dependent diffusion coefficient. Such a diffusion coefficient reflects the changes in the membrane composition along the permeation axis. One can observe on the scanning electron microscope photograph (Borys et al. 2011) of the magnetic membrane cross section that the feed side of the membrane is

Air Enrichment, by Polymeric Magnetic Membranes,

Fig. 2 Downstream absorption permeation curve

Air Enrichment, by Polymeric Magnetic Membranes, Table 1 Air enrichment for various membranes (Strzelewicz and Grzywna 2007)

Membrane	B[mT]	Oxygen content in permeate [%]
EC + 1.38 g Nd	0.79	40.7 ± 1.1
EC + 1.49 g Nd	1.25	43.8 ± 1.1
PPO + 1.80 g Nd	1.70	54.1 ± 1.4
PPO + 1.80 g Nd	2.70	61.9 ± 1.5

composed of a pure polymer while the output side consists of the polymer with dispersed magnetic granules. When the magnetic field is too strong, then magnetic aggregates are created, which influence the permeation of gases. Detailed analysis of the available data and microscopy images allowed to arrive four conclusions (Borys et al. 2011):

1. There are magnetic channels formed around the magnetic granules.
2. The channels provide high permeability “highways” for the diffusion of permeating molecules.
3. The oxygen molecules, due to their paramagnetic properties, stick to these “highways” for a longer time than nitrogen, which is probably based on the interaction with the Weiss molecular field of the permanent magnet.
4. The magnetic field induces aggregation between oxygen and nitrogen which enhances

the transport of both nitrogen and oxygen by prolonging their residence in the channel.

The method of air enrichment by magnetic membranes seems to be effective and efficient.

Air Gap Membrane Distillation (AGMD)

Maria Tomaszewska

Faculty of Chemical Technology and Engineering, West Pomeranian University of Technology, Szczecin, Poland

AGMD is a configuration of membrane distillation (MD) in which an air layer is interposed between a porous hydrophobic membrane and the condensation surface (Fig. 1). In the process, volatile compounds (including water) present in a warm feed evaporate at the liquid/vapor interface formed at the membrane surface. The vapor is transferred through the membrane pores and the gas gap and finally condenses on a cold surface inside the membrane module. The driving force of the mass transfer in AGMD is the difference in vapor pressure on both sides of the membrane.

The air gap significantly reduces the heat loss by the membrane material, therefore the permeate flux could increase. On the other hand air gap forms a barrier for the vapor, and due to the mass transfer resistance the permeate flux decreases with an increase of the air gap width (Table 1) (Alkhudhiri et al. 2012). When the gap width is changed, the mechanism of heat transfer

may be changed from pure conduction and diffusion to natural convection. The optimum of air gap width should be determined to achieve the best performance of the AGMD system taking into account a reduction of the heat loss and the value of the permeate flux.

Since in AGMD the permeate is condensed on the cold surface, the liquid permeate is separated from the membrane surface, which prevents the membrane wetting. Thus an important advantage of the process is the ability to remove the organic compounds from aqueous solutions.

The permeate flux in AGMD can vary from ca. 0.3 to 26 kg/m²h, depending on the operating conditions and feed composition. The rejection coefficient of nonvolatile species, e.g., NaCl, usually amounts close to 100 %. Generally, in AGMD the nonvolatile species present in a feed are almost completely retained, whereas volatile compounds are partially transferred through the membrane. The separation of compounds present in aqueous solutions using AGMD is based not only on the vapor/liquid equilibrium, but also the diffusion rate of the feed components through the gas filling the membrane pores and the air gap between the membrane and the condensation surface.

The air entrapped within the membrane pores and in the air gap can be considered as a stagnant film, thus the mass transfer in AGMD is generally described according to the ordinary molecular diffusion including both the air and noncondensable gases in the membrane pores and in the air gap. The air gap width is usually 10–100 times greater than the membrane thickness; therefore the membrane characteristics are usually neglected. In AGMD, the heat transfer includes the heat transfer through the feed boundary layer, through the membrane and the gas gap, condensation at the cold surface, and heat transfer through the condensate liquid boundary layer and to the cooling water. To optimize the AGMD systems, the effects of operating parameters should be taken into account (Khayet and Matsuura 2011).

The feed temperature strongly affects the permeate flux. Since the vapor pressure of aqueous solutions grows exponentially with temperature, the driving force increases for both water and volatile compounds present in a feed. Thus, the

Comments – the references can be found in the original paper

total permeate flux J_t (a sum of the water vapor flux J_w and the volatile compounds flux J_v) increases, but the selectivity of volatile solutes decreases with a feed temperature. The heat loss by conduction through the membrane material is lower at higher feed temperature which also explains the higher permeate flux.

An increase in the concentration of nonvolatile compounds in a feed reduces the J_t due to a decrease in the J_w . In the case of an increase of concentration of volatile compounds in a feed, the J_t and J_v increase, whereas the J_w decreases. It is associated with changes of the partial pressure of dissolved species and water. The selectivity of volatile compounds can be different depending on their properties and concentration in the feed and can be improved by an increase of their partial pressure by salt addition into a feed. Generally, a higher feed flow rate diminishes the effects of both temperature and concentration polarization and AGMD permeate flux increases. Different spacers can be applied to improve the hydrodynamic conditions. The effect of coolant temperature is not very significant because the heat transfer coefficient in the air gap dominates the overall heat transfer coefficient (Khayet and Matsuura 2011).

Air Gap Membrane Distillation (AGMD), Applications of

Maria Tomaszewska

Faculty of Chemical Technology and Engineering, West Pomeranian University of Technology, Szczecin, Poland

The separation using AGMD is based not only on vapor/liquid equilibrium but also on the diffusion rates of the feed components through the gas trapped in the membrane pores and the air gap between the membrane and the condensation surface. Nonvolatile compounds are rejected by a membrane in almost 100 %. Therefore, AGMD can be applied for desalination and production of high-purity water. A permeate with electrical conductivity as low as $4 \mu\text{S/cm}$ can be obtained from a solution with composition similar to seawater. Moreover, AGMD can be applied for the separation of volatile compounds. Since the vapor is condensed on the cold surface and the liquid permeate does not come into contact with a hydrophobic membrane, even the organic solutes can be separated without a risk of the membrane wetting. The air gap reduces considerably the heat loss and the temperature polarization which improve the separation efficiency of AGMD; however, this leads simultaneously to a significant decrease in the permeate flux. The decrease depends strongly on the width of the air gap. The air gap is about 10–100 times thicker than the membrane, so the

PTFE polytetrafluoroethylene, *PVDF* polyvinylidene fluoride

effect of air inside the membrane can be neglected. AGMD creates the opportunity for the separation of species forming the azeotropic solutions. It is attributed to the difference in the diffusion coefficients of volatile compounds present in a feed through the gas gap (Khayet and Matsuura 2011). Thus, AGMD can find the application in water and wastewater treatment, biotechnology, food industry, etc. (Table 1).

The plate and frame, tubular, capillary, and very frequently spiral wound modules equipped with porous hydrophobic membranes are used in AGMD.

The main area of AGMD application is desalination. The desalination pilot plants combining AGMD with solar energy collectors were developed, especially for operation in arid and semiarid remote regions with a lack of electricity and drinkable water but with high solar radiation (Table 2). The production of potable water, e.g., from plants installed in Jordan was of 100 L/day (utilizing brackish water) and 1 m³/day (Fig. 1) (utilizing untreated seawater from the Red Sea). The installations were equipped with AGMD spiral wound modules with area of 10–40 m², respectively. Long-term experiments have demonstrated that the average salt rejection was 98 % (Qtaishat and Banat 2012; Khayet and Matsuura 2011). Distillate conductivity of 3–5 µS/cm can be obtained for brackish water feeding. Despite the advantages such as the ability to desalinate high saline

feedwater, fitness for intermittent energy supply, and the ability to use direct solar heat without heat storage, the plants have not been commercialized or implemented in a large scale. This is mainly because reverse osmosis (RO) is considered as more economical and energy-efficient desalination process (Saffarini et al. 2012). However, the AGMD/solar energy systems are still in progress and find a growing interest.

Another field of AGMD application is food processing. Figure 2 presents the possibility of juice concentration by AGMD to achieve much higher feed concentration than using RO. Low processing temperature allows to concentrate the solutions sensitive to high temperature and provides a good quality of juice concentrate (Kimura and Nakao 1987). The concentration of milk demonstrated that the membranes were easily fouled by milk fat and the permeate flux decreased very fast (Khayet and Matsuura 2011).

Ethanol preferentially vaporizes from the aqueous feed and is concentrated in the permeate. Since in AGMD the liquid ethanol does not come into contact with a membrane, it can be separated from a fermentation broth and concentrated without a risk of the membrane wetting. It was found that a salt addition into diluted ethanol increases alcohol selectivity (Khayet and Matsuura 2011).

AGMD can be useful in breaking the azeotropic mixtures of water and hydrochloric or propionic acids. This phenomenon was associated

with the differences in the acid-air and water-air diffusion rates in the air gap. In AGMD the hydrochloric acid/water azeotrope was shifted to higher acid concentration, and the azeotrope was eliminated in the propionic acid/water system. It was found that the heavy gases such as SF₆ help more in eliminating the azeotropic point than the lighter ones as air or He (Khayet and Matsuura 2011).

AGMD was successfully used for the concentration of a mixture of HI and H₂SO₄, compounds of great interest for H₂ generation in thermochemical water-splitting cycle (Khayet and Matsuura 2011). AGMD has also a great potential in the application in the environment protection area. Therefore, this technique requires more studies, devoted especially to a long-term performance and membrane life.

PuriMem, LLC, Emmaus, PA, USA

The majority of air separation is done by cryogenic distillation; however, for several small applications a gas separation membrane is desirable. The key commercial gaseous products made from air by membranes are nitrogen, oxygen enriched air, and dry air. Further, gas separation membranes in hybrid system with a cryogenic process is used to produce Argon (Agrawal and Xu 1996) and with an adsorption process to produce high concentration oxygen enriched air (Choe et al. 1997).

In membrane nitrogen production systems (Drioli and Barbieri 2011), the compressed air is fed on one side of the membrane; oxygen, argon, carbon dioxide, and water which have higher permeation than nitrogen, permeate through the membrane leaving nitrogen behind. A schematic of the membrane nitrogen generation system is shown in Fig. 1.

The compressed air at a temperature of 80–100 °C and a pressure of about 1000 kPa (135–150 psi) is purified by the use of coalescing filter and fed to the membrane module. The productivity and purity of the nitrogen produced is controlled by the use of a product pressure valve. Membrane systems produce nitrogen at a concentration ranging from 95 % to 99.9 %. However, due to the modest selectivity (<8) of air separation membranes, production of high purity nitrogen is not economically favorable. Key producers of nitrogen separation membranes are Air Products, Air Liquide, and Ube. Other nitrogen membrane producers are: Generon Systems, Aquillo and Parker Heniffin.

Dry air with dew point up to -40 °C (-40 °F) is produced by removing moisture from the atmospheric air using a water permeable membrane which are either made of glassy polymers (polysulfone, polyimide, etc.) or fluorine containing ionomers. Schematic of a typical air drying system is shown in Fig. 2.

In air drying system, clean wet air is fed under pressure on one side of the membrane module and dry air at slightly reduced pressure is recovered as retentate. In some systems, an internal or external

Air Products, Fig. 2 Typical air drying system (Courtesy: AGC Chemicals Americas)

dry air sweep is used to prevent water buildup on the membrane in permeate, which retards membrane performance (Morgan et al. 1996).

In some instances, membrane systems are used to produce oxygen enriched air with oxygen concentration $<30\%$ O_2 . Mostly, rubbery membranes of modest selectivity (2–3) and high oxygen flux are used for this application³. The membrane system used is similar to that used for nitrogen production described above. Sometimes, use of vacuum on the permeate side is preferred over the use of a compressor for the production of oxygen enriched air.

Air separation technology is used for the production of oxygen, nitrogen, and rare gases that are present in air such as argon and neon. There are two fundamental approaches to air separation, which are cryogenic and non-cryogenic processes. The cryogenic process which is carried out in distillation column has the capability to deliver large and high purities of products, while the non-cryogenic which is based on absorption and membrane technologies is more suitable for on-site production, which is most common for small and medium throughputs.

Air Separation,
Fig. 1 Schematic representation of the oxygen transport in MIEC ceramic membrane

Membrane technology for air separation has developed rapidly in recent years. Polymeric and ceramic membranes have been used commercially for oxygen production. Polymeric membranes operate based on the difference in rates of diffusion of oxygen and nitrogen through a membrane. Due to the smaller size of the oxygen molecule, most membrane materials are more permeable to oxygen than to nitrogen. Materials such as polysulfone or acetate membranes make it possible to permeable oxygen five times than of nitrogen. Membrane units capable of producing nearly 600 tonnes per day nitrogen have been built (Castle 2002). A major benefit of polymeric membrane separation is the simple, continuous nature of the process and operation at near ambient conditions (Smith and Klosek 2001); however, the low separation factor of two to six limits the polymeric membrane to produce oxygen-enriched air rather than pure oxygen (Zhu et al. 2008).

Production of pure oxygen from air can be achieved by using ceramic membrane system at elevated temperatures, typically in the range of 800–900 °C (Hashim et al. 2011). The oxygen transporting through this type of membrane is in the form of oxygen ions instead of oxygen molecules; therefore, the pure oxygen is obtained. Enormous efforts have been directed to ceramic membranes with mixed ionic–electronic conducting (MIEC) characteristics. Among them, perovskite-type (ABO_3) ceramic membranes exhibit the highest oxygen permeability due to their high ionic and electronic conductivity. The perovskite oxide based on $\text{La}_{1-x}\text{A}_x\text{Co}_{1-y}\text{Fe}_y\text{O}_{3-\delta}$ achieved very high oxygen permeation fluxes as reported by Teraoka et al. (1985).

Interestingly, the oxygen separation from air in MIEC ceramic membrane system requires neither electrodes nor an external circuit to operate. As depicted in Fig. 1, the electronic conductivity itself performs as an internal short circuit that involves oxygen partial pressure gradient. The oxygen molecule permeates from the high oxygen partial pressure side to the low oxygen partial pressure side, while the overall charge neutrality is maintained by counterbalancing the flux of electrons (Liu and Gavalas 2005). Several industrial gas companies are working on developing ceramic membranes for oxygen separation from air at high temperatures. Air Products and Chemicals has developed an ion transport membrane (ITM) system, which is based on patented, high-temperature ceramic membranes for the production of oxygen from air separation (Hashim et al. 2011). Praxair is also working on oxygen-conducting ceramic membrane systems that are specially designed to separate oxygen from air at elevated temperature environment (Hashim et al. 2011).

Al₂O₃ Porous Membranes

Sophie Cerneaux

UMR 5635 ENSCM, CNRS, UM, Institut
Européen des Membranes, Montpellier, France

Synonyms

[Aluminum \(III\) oxide porous membranes or alumina porous membranes](#)

Characteristics

Al₂O₃ is an amphoteric oxide that exhibits polymorphic crystalline forms upon temperature treatment. A wide variety of alumina powders are commercially available with different particle sizes.

Alumina porous membranes are commercially available inorganic ceramic membranes widely used in membrane processes related to water treatment essentially. They are shaped in monolith, honey comb, flat, monochannel, and multichannel configurations or as thin films.

Alumina membranes may be prepared by anodic oxidation of aluminum foil to design well-ordered and straight pore channels in the membrane or by sol-gel route using colloids or Al molecular precursors to yield porous supported membranes. In addition, alumina macroporous supports are also used for multilayered structures of other oxide or non-oxide materials. More recently, alumina porous membranes found a new application as hard template for the fabrication of nanotubes and nanowires through

electrodeposition and alumina membrane etching (Burggraaf and Cot 1996; Lee and Pope 1994).

The filtration process and therefore the elimination of different species from polluted water, for example, strongly depend on the type of membrane used, its porosity, and pore size. As recommended by IUPAC, porous membranes are classified according to their connected pore size being microporous for pore diameters lower than 2 nm, mesoporous for pore diameters in the range 2–50 nm, and macroporous for pore sizes superior than 50 nm (Koros et al. 1996). Respectively, porous membranes will be applied to separation processes such as nanofiltration, ultrafiltration, and microfiltration.

The synthesis of macroporous and mesoporous membranes is often made by consolidation of particles followed by thermal removal of organic additives. Going to nanofiltration application, the microporous network is directly prepared from a sol containing particles lower than 10 nm followed by an appropriate sintering step.

Alamine 336,
Fig. 1 Schematic structure
 of Alamine 336

The IUPAC systematic name is *N,N*-dioctyl-1-octanamine (Fig. 1). Alamine 336 is colorless ($C_{24}H_{51}N$, CAS Reg. No. 1116-76-3) or light yellow liquid (mixture of Tri C8-10 Alkyl Amines, $C_{27}H_{57}N$ – CAS Reg. No. 57176-40-6, produced by Cognis Corp., now part of BASF). If released to air, estimated vapor pressure is about 0.007 Pa at 25 °C. It is moderately toxic by ingestion and intraperitoneal routes; when heated to decomposition, it emits toxic vapors of NO_x (Zhu et al. 2012). Manufacturing of Alamine 336 is possible by catalytic amination of octanol (Li et al. 2011) or by catalytic hydrogenation of caprylonitrile (Lazier 1940). It is used as the extractant for reactor fuel processing (Moyer and McDowell 1981), for dye identification (Puttemans et al. 1982), and for metal adsorption (Tasker et al. 2003) and recovery from diluted aqueous solutions (Kislik 2012; Coca et al. 1990; Sun and Lee 2011). Mixtures of Alamine 336 with meta-xylene can be successfully applied for extraction metal ions from their strong acidic aqueous chloride solutions (Sayar et al. 2007). Alamine 336 can be also used for specific extractions in biotechnology, e.g., separation of carboxylic acids (Tamada et al. 1990; Yordanov and Boyadzhiev 2004), and in supported liquid membranes (San Román et al. 2010; Dzygiel and Wieczorek 2010) (Table 1).

Albumin Purification with Affinity Membranes

Adil Denizli and Handan Yavuz

Department of Chemistry, Biochemistry Division, Hacettepe University, Ankara, Turkey

Nearly 175 years ago, a very accurate description of the properties of human serum albumin (HSA) was available (Ancell 1839). HSA is one of the most abundant proteins in plasma and, together with immunoglobulin, constitutes 80 % of all plasma proteins. In addition to plasma, HSA is also found in tissues and bodily secretions throughout the body. It has several physiological functions in vivo, which contribute significantly to colloid osmotic blood pressure and aid in the transport, distribution, and metabolism of many endogenous and exogenous substances (He and Carter 1992). The ethyl alcohol fractionation is the oldest process of industrial fractionation of blood proteins but it cannot produce sufficiently pure albumin (Stotz et al. 1990). Of all purification methods, chromatography may be the best candidate for minimizing process-generated albumin heterogeneity. Affinity chromatography is a well-established method for the purification of proteins, and it is based on highly specific molecular recognition. Conventional packed-bed column chromatography is often limited by long processing times due to low flow-rates, which result from the high pressure drop (Denizli et al. 1999). In order to overcome these operational limitations, microporous membrane adsorbers have been developed (Ghosh 2002). Microporous membranes as a support for chromatography have several potential advantages. A configuration in which the feed solution flows

through the membrane provides a very short, wide bed; thus, high velocities and very short residence times are attainable with modest transmembrane pressure drops. Elimination of diffusional resistance usually leaves a system controlled by much faster binding kinetics, thereby enabling adsorptive separation of proteins, typically, one-tenth the time common for packed columns. Adsorptive membranes exhibit high binding capacities similar in magnitude to packed columns and using stepwise elution, proteins can rapidly be concentrated tenfold or more with 85–100 % recovery. Analytical separations equivalent to those of column chromatography are reached by using sufficient numbers of membrane stacks and gradient elution methods. The linear scalability of the membrane systems further adds to the attractiveness of the technology. When dealing with viscous mediums such as blood, mass transfer in a diffusive-transport mode is more efficient, where the liquid is made to flow tangentially past the membrane surface while the adsorbate diffuses into the microporous membrane to meet the selective ligand immobilized there. Several ligands can be used for the affinity separation of albumin as summarized in Table 1.

Alcohol and Water Separation

Tadashi Uragami

Organization for Research and Development of Innovative Science and Technology (ORDIST), Kansai University, Suita, Osaka, Japan

Cross-linked poly(vinyl alcohol) (PVA) composite membranes have been used in commercial PV plants for dehydration of ethanol beyond the

azeotrope. However aqueous ethanol solutions that can be produced by bio-fermentation are dilute (about 10 wt.%). Therefore, if ethanol/water-selective membranes with high efficiency can be prepared, the distillation process in the first stage to obtain an azeotrope can be replaced ethanol-/water-selective membrane which is very advantageous for reduction of energy cost. There are fewer reports on ethanol-/water-selective membranes compared with those of water/ethanol-selective membranes. One reason why the development of efficient high-performance ethanol-/water-selective membranes is difficult can be attributed to the fact that ethanol has a larger molecular size than water and must be preferentially permeated through the membrane. In fact, permeation and separation in a pervaporation (PV) process through dense membranes are based on the solution-diffusion mechanism (Binding et al. 1961; Aptel et al. 1974). Therefore, when it is required that ethanol molecules with larger molecular size preferentially permeate from an aqueous ethanol solution, it cannot be expected to be separated by the diffusion process. Consequently, only a difference of solubility selectivity in the solution process in which both ethanol and water components are dissolved can contribute to the separation. Figure 1 shows the ethanol concentration in the

Alcohol and Water Separation, Fig. 1 Permeation and separation characteristics of aqueous ethanol solutions through a PDMS membrane during PV

permeate through a poly(dimethylsiloxane) (PDMS) membrane during PV and that sorbed into a PDMS membrane. These results support the hypothesis that the difference in the solubility of the permeants contributes to the ethanol/water selectivity. PDMS membranes show high ethanol/water selectivity, but their mechanical strength is weak, and it is difficult to prepare thin membranes from PDMS. In order to obtain both ethanol/water selectivity and mechanical strength, graft copolymers composed of PDMS macromonomer and vinyl monomers were synthesized.

Graft copolymer membranes, which were either ethanol or water selective, were prepared by copolymerization of a dimethylsiloxane (DMS) macromonomer with methyl methacrylate (MMA) (Miyata et al. 1995, 1996). Two glass transition temperatures (T_g) were observed at about 120 °C and -127 °C in the graft copolymer membranes. Transmission electron micrograph (TEM) demonstrated that the PMMA-g-PDMS membranes showed microphase-separated structures. When an aqueous solution of 10 wt.% ethanol was permeated through the PMMA-g-PDMS membranes by PV, the ethanol concentration in the permeate and the permeation rate increased drastically with the DMS content in the copolymer. In particular, at a DMS content of less than

Alcohol and Water Separation, Fig. 2 Effects of the DMS content on the normalized permeation rate (O) and separation factor (●) through the PMMA-g-PDMS membrane during PV. Feed: aqueous solution of 10 wt.% ethanol. Dashed line is the feed composition

40 mol%, water permeates preferentially from an aqueous solution of 10 wt.% ethanol, whereas membranes with more than about 40 mol% of DMS are ethanol/water selective, as shown in Fig. 2. The change in the ethanol/water selectivity of the PMMA-g-PDMS membranes can be explained by a microphase-separated polymer structure using Maxwell's model and a combined model consisting of both parallel and series expressions. Furthermore, image processing of TEMs allowed the determination of the percolation transition of the PDMS phase at a DMS content of about 40 mol%. These results suggest that the continuity of the PDMS phases in the microphase-separated PMMA-g-PDMS membranes directly affects their ethanol/water selectivity for aqueous ethanol solutions (Miyata et al. 1995, 1996).

In Table 1, the performance of the ethanol-/water-selective polymer membranes is compared. As can be seen in this Table, the addition of PFA-g-PDMS to the PTMSP membrane in PV was very effective, the application of TDEV method to the membrane separation technique was also very interesting for the enhancement of the ethanol/water selectivity for the ethanol/water mixtures, and in particular the application of porous PDMS membrane to temperature-difference controlled evaporation (TDEV) (Uragami 1998, 2005, 2006a, b, 2008, 2010, 2011; Uragami and Shinomiya 1991, 1992; Uragami and Tanaka 1991, 1993, 1994; Uragami et al. 2002; Uragami and Morikawa 1989) was a very excellent performance for the ethanol/water mixtures.

Synonyms

Alcohol separation by [Membrane Distillation \(MD\)](#); Alcohol separation by [Pertraction](#); Alcohol separation by [Pervaporation \(PV\)](#); Alcohol separation by [Vapor permeation](#)

Biochemical, i.e., fermentative, production of alcohols and other solvents has been increasing significantly in the last years. Recovery and purification of alcohols from dilute aqueous solutions obtained after fermentative solvent production is energy intensive and expensive. For example, conventional distillation is stated to be an efficient alcohol separation technique for the ethanol in concentration range from 10 to 85 wt.% (Huang et al. 2008). The use of membrane operations is however seen as a more cost- and energy-efficient method over conventional distillation in the case

of dilute alcohol solutions (excluding methanol). Especially the use of selective membranes for ethanol or *n*-butanol removal from dilute fermentation broths has gained a lot of interest recently.

Membrane Operations

The most used membrane operations for alcohol removal include separation techniques like filtration, membrane distillation (also known as membrane evaporation), pertraction, pervaporation (PV), and vapor permeation (VP). Micro-, nano-, and ultrafiltration are used in solid-liquid separations mainly as a pretreatment step prior to the alcohol removal. In pertraction, the membrane is placed between fermentation broth and extractant. The membrane passes through the alcohol enabling its extraction, while other components such as nutrients and intermediate products remain in the feed side. In pervaporation and vapor permeation, desired minor compounds from a feed solution are diffused through the hydrophobic membrane and desorbed in the permeate side of the membrane as a vapor which can then be condensed back to the liquid state by, e.g., a condenser (Schäfer and Crespo 2005). Feed solution is in a liquid phase in PV applications and in a vapor phase in VP processes. The driving force, a chemical potential difference of the compounds, is obtained by applying different partial vapor pressures of compound(s) on the opposite sides of the membrane: The feed side is under atmospheric pressure, whereas vacuum or very low pressure is applied in the permeate side. Because only permeated compounds are evaporated in pervaporation, lower energy, capital, and processing costs can be obtained as compared to other separation techniques.

Membranes

Membranes used in alcohol removal are hydrophobic, i.e., organophilic, having preferential permeation for organic compounds instead of water.

Nonporous membranes are used in PV and VP applications, while membrane distillation operations are performed with semipermeable porous membranes. The semipermeable polymeric membranes used mostly are made of polydimethylsiloxane (PDMS). Other used materials include, e.g., polyether block amide (PEBA), polyoctylmethyl siloxane (POMS), polypropylene (PP), polytetrafluoroethylene (PTFE), polytrimethylsilylpropyne (PTMSP), polyvinylidene fluoride (PVDF), and liquid membranes. Ceramic and zeolite membranes are also available. Composite membranes having a porous support layer and a thin separation layer are widely used due to better separation efficiency and membrane stability. Besides a good chemical, mechanical, and thermal stability, membranes should also have high flux and selectivity toward alcohols. Membrane modules can be in the form of flat sheets or plates, spiral wounds, envelopes, or (hollow) tubular modules (Brüschke 2001).

Advantages and Disadvantages

Advantages of membrane operations include the possibility to be used also in the case of azeotropic mixtures and for the separation of volatile organic compounds. In addition, combining the membrane operation with a fermentor as a hybrid process as in situ product removal (ISPR) enables obtaining an increased yield in fermentation and more efficient separation efficiency. Other hybrid processes are typically a membrane operation combined with distillation or with other membrane technique. The main disadvantage in the operation is the fouling tendency of the membrane surface or of the pores inside the membrane, in addition to concentration polarization. Fouling can be reduced by improved membrane module design or operating procedures (Vane 2005).

Industrial Applications

In commercial scale, ethanol is usually first dehydrated by distillation up to the ethanol

concentration of around 92.4 wt% (below the azeotropic point), and further dehydration is done by other separation techniques including, e.g., adsorption by molecular sieves. Especially, pervaporation and vapor permeation are more energy-efficient and promising techniques, but only a few number of pilot- or industrial-scale facilities for alcohol separation are in use, despite the active research going on in laboratory scale. Hence, there is still need for research and development activities to obtain feasible industrial-scale applications.

Alginate

Emma Piacentini

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Alginates are unbranched anionic polysaccharides consisting of 1→4 linked β -D-mannuronic acid (M) and its C-5 epimer α -L-guluronic acid (G) (Fig. 1).

The natural copolymer is an important component of algae such as kelp and is also an exopolysaccharide of bacteria including *Pseudomonas aeruginosa*. The copolymer composition, sequence, and molecular weights vary with the source and species that produce the copolymer. The molecular weights of commercially available sodium alginates range between 32,000 and 400,000 g/mol. The viscosity of alginate solutions increases as pH decreases and reaches a maximum around pH 3–3.5, as carboxylate groups in the alginate backbone become protonated and form hydrogen bonds. The solubility of alginates in water is governed by three parameters, i.e., (a) pH of the solvent, (b) ionic strength of the medium, and (c) the presence of gelling ions in the solvent. To make alginates soluble, it is essential that the pH be above a certain critical value and the carboxylic acid groups be deprotonated. Changing the ionic strength of the medium affects solution properties such as polymer conformation, chain extension, viscosity, and therefore solubility. Alginates gel in the presence of divalent cations such as Ca^{2+} , Sr^{2+} , and Ba^{2+} . It is therefore

necessary to have an aqueous solvent free of cross-linking ions to enable dissolution. The solubility of alginates in organic media requires formation of a tetrabutylammonium (TBA) salt. The solubility of alginates depends strongly on the state of the backbone carboxylic acid groups. Alginic acid with its carboxylic acid groups in their protonated form was not fully soluble in any solvent system examined, including water.

Chemical modification or derivatization of alginates is used as a tool to attain one of two ends, i.e., (a) enhance existing properties (such as improvement of ionic gel strength by additional covalent cross-linking, increase hydrophobicity of the backbone, improve biodegradation, or achieve greater HAP nucleation and growth) or (b) introduce completely new properties otherwise not existing in unmodified alginates (such as afford anticoagulant properties, provide chemical/biochemical anchors to interact with cell surfaces, or bestow temperature-dependent characteristics such as lower critical solution temperature). Alginate derivatization (Pawar and Edgar 2012) includes acetylation, phosphorylation, sulfation, hydrophobic modification, attachment of cell signaling molecules, covalent cross-linking, and graft copolymerization. In particular, amphiphilic alginate derivatives have been synthesized by introducing hydrophobic moieties (e.g., alkyl chains, hydrophobic polymers) to the alginate backbone. These derivatives can form self-assembled structures such as particles and gels in aqueous media and have potential in many drug delivery applications. Alginate derivatives containing cell-adhesive peptides have been gaining significant attraction recently. These derivatives are typically prepared by chemically introducing peptides as side chains, using carbodiimide chemistry to couple via the carboxylic groups of the sugar residues. Since alginate inherently lacks mammalian cell adhesivity, appropriate ligands are crucial to promote and regulate cellular interactions, especially for cell culture and tissue engineering applications. Peptides including the sequence arginine-glycine-aspartic acid (RGD) have been extensively used as model adhesion ligands, due to the widespread presence of integrin receptors for this ligand on

Alginate, Fig. 1 Components of alginates

various cell types. RGD-containing peptides can be chemically coupled to the alginate backbone using water-soluble carbodiimide chemistry.

Alginate is typically used in the form of a hydrogel. Hydrogels are three-dimensionally cross-linked networks composed of hydrophilic polymers with high water content. Hydrogels are often biocompatible, as they are structurally similar to the macromolecular-based components in the body, and can often be delivered into the body via minimally invasive administration. Alginate chelates with divalent cations to form hydrogels. Gel formation is driven by the interactions between G blocks which associate to form tightly held junctions in the presence of divalent cations. In addition to G blocks, MG blocks also participate, forming weak junctions. Thus, alginates with high G contents yield stronger gels.

Chemical and/or physical cross-linking of hydrophilic polymers are typical approaches to form hydrogels, and their physicochemical properties are highly dependent on the cross-linking type and cross-linking density, in addition to the molecular weight and chemical composition of the polymers. The most common method to prepare hydrogels from an aqueous alginate solution is to combine the solution with ionic cross-linking agents, such as divalent cations. The affinity of alginates toward divalent ions decreases in the following order: $\text{Pb} > \text{Cu} > \text{Cd} > \text{Ba} > \text{Sr} > \text{Ca} > \text{Co, Ni, Zn} > \text{Mn}$. Ca^{2++} ; however, it is the most commonly used cation to induce alginate gel formation. Calcium cross-linking of alginates can be performed by two methods. The first is a “diffusion” method, wherein cross-linking ions diffuse into the alginate solution from an outside reservoir. The second is the “internal setting” method, where the ion source is located within the alginate solution and a controlled trigger (typically pH or solubility of the ion source) sets off the release of cross-linking ions into solution. Diffusion set gels are typically made by dropping a Na-alginate solution into a CaCl_2 bath. Internal set gels typically use insoluble calcium salts such as CaCO_3 as a calcium source. The gelation rate is a critical factor in controlling gel uniformity and strength when using divalent cations, and slower gelation

produces more uniform structures and greater mechanical integrity. One critical drawback of ionically cross-linked alginate gels is the limited long-term stability in physiological conditions, because these gels can be dissolved due to release of divalent ions into the surrounding media due to exchange reactions with monovalent cations and the hemostasis promoted by the calcium ions released from the gel that serves as a matrix for aggregation of platelets and erythrocytes. Covalent cross-linking has been widely investigated in an effort to improve the physical properties of gels for many applications, including tissue engineering. However, covalent cross-linking reagents may be toxic, and the unreacted chemicals may need to be removed thoroughly from gels. The inability to dissociate and reform bonds leads to significant elastic deformation. Thermosensitive hydrogels have been widely investigated to date in many drug delivery applications, due to their adjustable swelling properties in response to temperature changes, leading to on-demand modulation of drug release from the gels. When alginate is modified with cell adhesion ligands, the ability of cells to bind multiple polymer chains can lead to long-distance, reversible network formation even in the absence of chemical cross-linking agents. Cells added to an RGD-modified alginate solution form a uniform dispersion within the solution, and this system subsequently generates the cross-linked network structure via specific receptor-ligand interactions without using any additional cross-linking molecules. In contrast, cells added to non-modified alginate solutions aggregate and form a nonuniform structure, due to the dominance of cell-cell interactions in that system. This gelation behavior is shear reversible and can be repeated multiple times. Once the gel structure is broken down by applying shear forces, cross-linked structures are recovered within a few minutes. This behavior is governed by the weak and reversible ligand-receptor interactions in the system. This system might be ideal for cell delivery in tissue engineering because a gel can flow like a liquid during injection into the body but solidify once it is placed in the body.

Large pellets (greater than 1.0 mm in diameter) are conventionally prepared using a simple

syringe or pipette. Droplets of sodium alginate solution are extruded into a divalent cross-linking solution, and pellets formed are then allowed to cure in the cross-linking solution (varying from a few minutes to hours), rinsed with water, and air-dried. Micropellets (less than 0.2 mm in diameter) can be prepared using atomization, emulsification, and coacervation methods.

Polysaccharides undergo hydrolytic cleavage under acidic conditions. The mechanism of acid hydrolysis of the glycosidic bond involves three steps: (1) protonation of the glycosidic oxygen to give the conjugate acid; (2) heterolysis of the conjugate acid forming a nonreducing end group and a carbonium-oxonium ion; and (3) rapid addition of water to the carbonium-oxonium ion, forming a reducing end group. The enzymatic degradation of alginates by lyase occurs by a β -elimination mechanism resulting in unsaturated compounds. The mechanism of β -elimination involves abstraction of the proton at the C-5 position, which is enhanced by the electron-withdrawing effect of the carbonyl group at C-6 position. Alginates chain degradation can occur also at neutral pH values in the presence of reducing compounds such as hydroquinone, sodium sulfite, sodium hydrogen sulfide, cysteine, ascorbic acid, hydrazine sulfate, and leucomethylene blue that also caused degradation in alginates. The mechanism of degradation involves the formation of a peroxide leading to free radical creation, which eventually causes breakdown of the alginate chain.

Alginate is inherently nondegradable in mammals, as they lack the enzyme (i.e., alginase) which can cleave the polymer chains, but ionically cross-linked alginate gels can be dissolved by release of the divalent ions cross-linking the gel into the surrounding media due to exchange reactions with monovalent cations such as sodium ions. An attractive approach to make alginate degradable in physiological conditions includes partial oxidation of alginate chains. Slightly oxidized alginate can degrade in aqueous media, and these materials have demonstrated potential as a delivery vehicle of drugs and cells for various applications. Alginate is typically oxidized with sodium periodate.

The chemical and physical properties of alginates resulted in many commercial applications (Goh et al. 2012; Lee and Mooney 2012):

- (i) Food and beverage industry (stabilizers, thickeners in the preparation of drinks, ice cream, and jelly; encapsulation material of yeast cells in ethanol production)
- (ii) Pharmaceutical industry (encapsulation material in cell culture and transplantation, mold in dental impression material, adhesive agent and sustained release in tablets, hemostatic and absorbent in wound dressing)
- (iii) Other industries (adhesive agent and filler in paper industry, stabilizer and suspending agent in paint industry)

Vertically aligned carbon nanotube

Main Text

Carbon nanotubes (CNTs) are allotropes of carbon in which the carbon atoms form a hexagonal sheet of sp^2 bonds (analogous to graphite) which is seamlessly rolled up into a cylinder that can be microns long but is only nanometers in diameter (Yamamoto et al. 2008). Following typical synthesis procedures, CNTs exist as a tangled web of randomly oriented fibers. For many applications, the CNTs are required to be aligned with either horizontal or vertical alignment (Fig. 1).

Horizontally aligned CNTs are of particular importance in the generation of field effect transistors and conductive wires based upon CNTs. CNTs can be horizontally aligned via a range of processes including spin coating, filtering, magnetic field alignment, and drying-induced and chemical vapor deposition (CVD) (Dai 2001; Joselevich

et al. 2008). Horizontal CNTs can form a dense, flexible, stable mat (called a “bucky paper”) which can potentially be used as a membrane as the space between the CNTs is generally quite small (<50 nm) (Dumée et al. 2010; Sears et al. 2010).

Vertically aligned CNTs can be prepared via the CVD growth of CNTs on pre-patterned substrate supported catalyst nanoparticles. Vertically aligned CNTs produced via this method have been grown greater than 1 mm in length (Joselevich et al. 2008). Alignment is enhanced via the use of a strong electric field such as in plasma-enhanced CVD. Vertical alignment is of importance in the fields of field emission, chemical sensing, and CNT nanofiltration membranes (Endo et al. 2008; Shearer et al. 2012). CNT nanofiltration membranes are of particular interest as molecular dynamics simulations have shown that water can flow through CNTs at a

Aligned Carbon Nanotube, Fig. 1 SEM image CNTs produced via CVD showing (a) randomly entangled, (b) horizontally aligned, and (c) vertically aligned

remarkable rate (Hummer et al. 2001), while the flow of contaminants is restricted by the nano-size of the CNT inner pore (~ 1 nm). The fabrication of such a membrane required vertically aligned CNTs, encased within an impermeable matrix such that flow can only occur through the CNT inner pore. This is experimentally quite difficult, but a few reports with promising results have been published (Majumder et al. 2005; Holt et al. 2006; Wu et al. 2010).

Alkaline fuel cell (AFC) is a fuel cell type which utilizes alkaline electrolyte, usually potassium hydroxide. It consumes hydrogen and oxygen producing only water, heat, and electricity. Depending on a concentration of potassium hydroxide, AFC can operate at temperatures between 60 °C and 250 °C. The fuel cell reactions are as follows:

The main ionic charge carriers are OH^- ions which mitigate from the cathode to the anode. Water is formed at the anode side and has to be removed from the system in order to prevent KOH dilution. The AFC has improved cathode performance compared to acidic fuel cells due to more favorable oxygen reduction reaction kinetics. For this reason, AFC can achieve higher efficiency, i.e., higher voltage at comparable current densities than other fuel cell types. It has very long operating life time, e.g., 15,000 h have been demonstrated (Cifrain and Kordesch 2003). Furthermore, alkaline conditions allow application of nonprecious metal catalysts which could reduce significantly the material costs of this fuel cell. One of major disadvantages of AFC is its low CO_2 tolerance due to formation of carbonates according to:

The carbonates have low solubility in strong alkaline environments forming crystals, capable of

blocking of electrolyte pathways. The low CO₂ tolerance and the application of liquid electrolyte are two main hurdles for the broader commercialization of these systems. However, due to its high efficiency and high power density, AFC found applications in aerospace industry, e.g., they were employed on the Apollo missions as well as on the Space Shuttle orbitals. For other examples of developed AFC systems, please see Cifraín and Kordesch (2003) and Gülzow (2012).

Hydrogen and oxygen gases in the AFC are separated by a membrane. Usually permeable membranes also called diaphragms have been used (Gülzow 2012). A common diaphragm material up to 1980s was asbestos which due to health and environmental concerns is nowadays abandoned. Alternative materials are different polymer materials like porous polyethylene plates, nonwoven polypropylene, and similar. Potassium hydroxide electrolyte wets the diaphragm pores in order to ensure its ionic conductivity. For a good fuel cell performance, the electrolyte resistance induced by diaphragm has to be minimized. This resistance is influenced by the thickness of the diaphragm material, its pore size and tortuosity, and the KOH concentration. Since liquid electrolyte causes some practical problems in AFC usage, new developments go into direction of alkaline polymer electrolyte membranes which, in addition to separation, possesses ionic conductivity in the absence of liquid electrolyte. Currently there is no long-term stable membrane functioning without a liquid electrolyte phase.

Alkane and Alkene Separation by Membrane Operations

Chen Zhang

School of Chemical and Biomolecular Engineering, Atlanta, GA, USA

Alkenes (e.g., ethene, propene, butadiene, and butenes isomers) are extremely important building blocks in petrochemical industries with many derived chemicals and polymers. Traditionally, alkenes are recovered from alkene/alkane mixtures produced by cracking hydrocarbon feedstocks (e.g., ethane, LPGs, and naphtha). Alkene/alkane separations (e.g., separation of ethene/ethane, propene/propane, and butadiene/crude C₄) are traditionally performed on a massive scale by distillation, which are extremely energy intensive due to these components' close volatilities. For example, propene/propane separation was credited to be the most energy intensive commercially practiced distillation (Jarvelin and Fair 1993).

Membrane gas separations, among other competing alternatives (i.e., adsorptive separation and chemical absorption), can be used to either retrofit or replace existing distillation columns to make commercial alkene/alkane separations more energy efficient. Compared with well-developed membrane gas separations such as air separation, membrane-based alkene/alkane separation is more challenging. The feeds are highly condensable and usually under high pressure (or in liquid state), requiring that membrane materials must be sufficiently robust without being plasticized. Among alkene/alkane separations, ethene/ethane and propene/propane are most extensively studied with membranes. Conversely, membranes are less commonly considered for separations of C₄ and heavier alkene/alkane mixtures due to their much lower diffusivities and correspondingly unattractive productivities. Membrane separations are based on differences in how fast the penetrants diffuse through the membrane (i.e., diffusion selectivity) and/or how much they sorb in the membrane (i.e., sorption selectivity). For example, propene molecule is slimmer than propane

molecule. Remarkable propene/propane diffusion selectivity is possible for materials with rigid structures and properly tailored ultramicropores. Additionally, propene is slightly polar and a limited (<10) propene/propane sorption selectivity may be achieved with polar materials (e.g., cationic zeolites with high Al/Si ratio).

Membranes for alkene/alkane separations can be categorized into two classes: membrane separations based on sorption-diffusion and others based on facilitated transport. The majority of membranes in the first category achieve the separation relying on diffusion selectivity. Polymer membranes, despite their excellent scalability, are incapable of offering attractive alkene/alkane selectivity without significantly compromising their permeability due to the permeability-selectivity trade-off (Burns and Koros 2003). Additionally, uncrosslinked polymer membranes may be plasticized with high-pressure alkene/alkane feeds, resulting in significant selectivity loss. On the other hand, membranes derived from more rigid molecular sieving materials (e.g., zeolites, metal-organic frameworks [MOFs], zeolitic imidazolate frameworks [ZIFs], and carbon molecular sieves [CMS]) can offer simultaneously high permeability and selectivity. However, fabrication of molecular sieve membranes is usually difficult and many technical challenges must be solved to deliver such performance economically on a large scale. Among molecular sieve membranes, CMS membrane is the most promising as it can be conveniently realized in the scalable hollow fiber geometry by pyrolyzing polymer precursor hollow fibers. A compromise to address the limitations of both polymer membrane and molecular sieve membrane is mixed-matrix membrane (Adams et al. 2013), which are formed by dispersing molecular sieve particles/platelets in polymer matrices. Selectivity and/or permeability of mixed-matrix membranes may be substantially enhanced over the polymer matrices and in the meantime, the membrane can still be inexpensively processed into hollow fibers (Zhang et al. 2014).

Facilitated transport membrane is another class of membrane studied for alkene/alkane

separations (Faiz and Li 2012). Alkene transport in such membranes is assisted by carriers (e.g., Ag^+ ions) that reversibly react with alkenes through π -complexation. Amazing alkene permeability and alkene/alkane selectivity can be achieved in facilitated transport membranes at the same time. Nevertheless, the carriers may be irreversibly deactivated by certain impurities (e.g., hydrogen, hydrogen sulfide, and acetylenes) in the feed, resulting in permanent loss in both alkene permeability and alkene/alkane selectivity. While in some cases membrane performance may be partially recovered by periodically recharging the carrier, such approach may not be practical for large-scale applications.

Alkene Oxidative Dehydrogenation by Membrane Reactor

Miguel Menendez

Department of Chemical and Environmental Engineering, University of Zaragoza, Zaragoza, Spain

Alkanes are converted to olefins in the chemical industry because of the high demand of polyolefins, such as polypropylene or polybutadiene, and

Alkane Oxidative Dehydrogenation by Membrane Reactor,
Fig. 1 Scheme of a membrane reactor for the selective oxidation of hydrocarbons with a distributed feed of oxygen

also because olefins are the starting materials for many other chemicals. These reactions can be represented as

A common characteristic of these reactions is the achievable conversion being limited by thermodynamic equilibrium. Two options to increase the conversion are

- Using a membrane reactor where H_2 is removed from the reactor. This will increase the achievable conversion according to the Le Chaterlier's principle. Any material which can remove hydrogen selectively can be used, but Pd and Pd alloys are the most employed. The preparation of this kind of membranes has been widely described (Basile and Gallucci 2011).
- Adding an oxidizing agent (e.g., oxygen) to the reaction, in order to form water instead of hydrogen, the resulting reaction would be:

This approach has the advantage of being thermodynamically favored but has the problem that simultaneous formation of carbon oxides reduces the selectivity.

A way to improve the selectivity is to use a membrane reactor, where the membrane

distributes oxygen along a packed bed of catalyst. This improvement is based on the *favorable effect of low oxygen partial pressure* on the selectivity. In fact, for many catalysts the observed reaction order respect to oxygen for the above reaction is lower than for the formation of CO and CO_2 . This observation implies that low partial pressure of oxygen increases the selectivity to olefins.

This general principle has been applied for the oxidative dehydrogenation of ethane, propane, and butane, with successful results in all cases (Coronas and Santamaría 1999). Details of the results obtained with membrane reactors with propane and butane (oxidative dehydrogenation and oxidation to maleic anhydride) are described in specific chapters.

A general scheme of a membrane reactor for this kind of reactions is shown in Fig. 1.

The oxygen containing feed is usually introduced through the shell side. A porous membrane distributes this oxygen along the catalyst bed, keeping a low partial pressure of oxygen in all the beds. A feed containing the hydrocarbon is fed to the tube side, i.e., to the catalyst bed. The reaction products are removed at the exit of the catalyst bed.

As an alternative to porous membranes, dense ceramic membranes can provide an additional advantage: the separation of oxygen-nitrogen mixtures (Hashim et al. 2011). This would decrease the cost of oxygen separation.

Alumina Membranes

Bo Wang

Department of Chemical Engineering, Imperial College London, London, UK

Alumina membranes are membranes made of high-purity (mostly >97 %) aluminum oxides (alumina). They belong to the categories of ceramic membranes and in most cases, microfiltration and ultrafiltration membranes. Pure alumina membranes are predominant in all kinds of commercial ceramic membranes, and most other commercial ceramic membranes, if using other materials as the separation coating, are based on alumina membrane support.

Advantages and Disadvantages

Alumina membranes are chemically inert and mechanically strong, and also thermally stable, therefore they can be used under very harsh conditions such as aggressive chemical environments and elevated temperatures, making them versatile in various industrial processes. Their strong mechanical properties allow them to be operated under high pressures and high feed flow rates to achieve high productivity and to tolerate high solid contents in the feed.

The high fabrication cost is a major obstacle for alumina membranes to expand its market share. Although alumina is widely available, the complicated fabrication process and high energy consumption for sintering lift significantly the total

membrane cost, making it about one order of magnitude higher than its polymeric counterparts. However, because of much longer lifetimes and higher fluxes of alumina membranes, the long-term operating cost of alumina membrane plants is comparable with polymeric membrane plants, no mention there are many scenarios in which only alumina/ceramic membranes can be used.

Membrane Designs and Fabrication

Most alumina membranes use asymmetric membrane architectures. Coarse alumina particles are used for the supporting layer to provide mechanical strength, and the transport resistance in this layer is usually low due to its big pore size; fine alumina particles are coated on top of the support to form a thin separating layer to reach desired pore sizes and high fluxes; and depending on the pore size difference between the top and the supporting layer, one or few transition layers might be used between the top and supporting layers to avoid coating defects and to increase adhesion between layers.

Alumina membranes may adopt a tubular shape, plate shape, or monolithic multichannel design. The latest is the most commonly used design in industry because it provides higher membrane area per unit volume, therefore reduces the size of the separation plant and operating costs. Some commercial products can achieve an area to volume ratio of $800 \text{ m}^2/\text{m}^3$ with the monolithic design, which is comparable with spiral wound polymeric membrane modules.

Fabrication of alumina membranes usually involves several forming and sintering steps due to their multilayer asymmetric membrane architectures, and the total production process is often longer than 1 week. The supporting layer can be formed by extrusion (for tubular or monolith designs) or by pressing (for plate or disk designs), followed by partial sintering at a high temperature (up to 1600°C) to achieve a high strength and porous structures. Transition layers and the top layer then can be coated on the support, also followed by sintering after each coating. Depending on the pore size, two types of alumina

could be used for the top layer coating: for microfiltration membranes whose pore size is larger than 100 nm, α -alumina is used; for ultra-filtration membranes whose pore size is smaller than 100 nm, γ -alumina or a mixture of α and γ types are often used.

There are also other fabrication techniques that can produce unique alumina membranes, for example, the anodic alumina membranes that have straight cylindrical pores and asymmetric alumina membranes made by single-step phase inversion/sintering methods. These membranes have shown good potential in filtration but have not been widely accepted as a feasible replacement of conventional alumina membranes yet.

Applications

Alumina membranes are widely used in water and wastewater treatment, pharmaceuticals, food processing, chemical processing, and others. Production of drinking water and wastewater treatment are the most important applications, which occupy about half of the market share of alumina membranes. The stable pore structure of alumina membranes even under high pressures and abrasive conditions guarantees constant quality of the permeate and makes it preferable in the scenarios where quality control is crucial, such as in drinking water production and food industry. And the natural hydrophilic surface of alumina offers better anti-fouling property than polymeric membranes; therefore its usage in wastewater treatment is expanding rapidly; and in some other heavy-duty filtration processes such as treating produced water from oil fields, alumina membranes have been dominant.

Americium Separation by Membrane Operation

- P. K. Mohapatra
Radiochemistry Division, Bhabha Atomic
Research Centre, Mumbai, Maharashtra, India

Americium (Am) is the first among the transplutonium elements, produced in nuclear reactors in large quantities. Due to long half-lives of its isotopes ($t_{1/2}$ of ^{241}Am , 432 y; ^{243}Am , 7370 y), this element can have long-term hazards to the environment if not separated from the radioactive wastes before their disposal. Separation of Am mostly involves solvent extraction-based methods involving specially designed ligands for Am uptake. Membrane-based separation has been used for Am separation using pressure-driven techniques such as nanofiltration, facilitated by complexation (Favre-Réguillon et al. 2007). However, selectivity factors in such separation systems are not encouraging. Liquid membrane-based separation systems, with Am-specific carrier extractants, are reported to give better decontaminations.

Some of the first studies on Am transport using supported liquid membranes include the work of Danesi, who used CMPO (carbamoylmethylphosphine oxide) as the carrier extractant (Danesi et al. 1983). Feed solutions containing LiNO_3 resulted in highly encouraging

Am transport rates which were significantly affected in the presence of nitric acid in the feed, attributed to the cotransport of nitric acid. The Am transport rates could be improved by using a second membrane in parallel containing Primene JM-T as the carrier extractant for selective transport of nitric acid (Chiarizia and Danesi 1987). In another study, triphosphine trioxide extractants have been employed for Am(III) transport from NaNO_3 solutions with encouraging results (Cristau et al. 1999). Other extractants such as tetra-alkyl malonamides and diglycolamides have shown comparable or even better transport efficiency for Am as compared to CMPO. Malonamides such as DMDBTDMA (N,N'-dimethyl-N,N'-dibutyltetradecyl malonamide) and DMDOHEMA (N,N'-dimethyl-N,N'-dioctylhexylethoxymalonamide) are reported to be quite efficient for Am(III) transport (Sriram et al. 2000; Patil et al. 2013). TODGA (N,N,N',N'-tetraalkyldiglycolamide) has been found to be one of the best carriers for Am(III) transport due to significantly lower acid cotransport as compared to CMPO or malonamides (Ansari et al. 2009).

TODGA-based hollow-fiber supported liquid membrane system has been successfully used in a mini pilot-scale processing of synthetic high-level waste (Ansari et al. 2011). A series of studies have indicated that the diluents play a significant role in Am transport rates which are mainly due to two factors: (i) nature of the extracted species and (ii) diffusivity of the extractable complex which is based on the viscosity of the medium (Panja et al. 2012).

Am(III) separation of trivalent lanthanides has also been studied using various Am(III) selective extractants such as Cyanex 301 (Hoshi et al. 2000), BTP (Geist et al. 2005), etc. In one of the early reports on Am(III)–Eu(III) separations using liquid membranes (Novikov and Myasoedov 1987), almost no transport of Am(III) was observed while effecting complete quantitative Eu(III) transport using a feed composition of 0.01 M DTPA, 0.5 M citric acid, 0.5 M NaNO_3 at pH 2.9, and 1 M HDEHP as the carrier extractant. Cyanex 301 has been used for highly selective Am(III) transport of a feed also containing several trivalent lanthanide ions (Fig. 1; Bhattacharyya et al. 2006). Oxidation

Americium Separation by Membrane Operation,

Fig. 1 Gamma ray spectrum of the feed and receiver solutions measured using HPGe detector (Bhattacharyya et al. 2006)

to the +4 and +6 states reportedly enhanced Am transport rates due to higher extraction efficiencies of these ions. Tri-*n*-octylamine containing liquid emulsion membrane (LEM) systems has been used for the transport of Am(IV) which was done using phosphotungstate (Myasoedov et al. 1990). In another report (Mikheeva et al. 1994), the transport of hexavalent Am by electrochemical oxidation followed by simultaneous transport using HDEHP as the carrier.

There are several reports on the Am(III) recovery from acidic feeds using liquid emulsion membranes (LEM) using extractants such as HDEHP, PC-88A, and TODGA as well. Usually, the LEM methods are much faster as compared to the SLM-based separation methods which are due to highly dispersed globules containing the internal phase as the strippants present in the emulsion which effect rapid mass transfer. In a recent study, multifunctional ligands such as the calixarenes anchoring diglycolamide functional groups have shown improved transport behavior as compared to the simple extractants (Ansari et al. 2013). The liquid membrane methods with lower flux as compared to the solvent extraction methods can be used for pre-concentration and separation of Am from dilute solutions including environmental samples and radioactive wastes.

Ammonia Decomposition in Catalytic Membrane Reactors

Toshinori Tsuru

Department of Chemical Engineering, Hiroshima University, Higashi-Hiroshima, Japan

Recently, NH_3 has been proposed as a H_2 carrier in a promising solution that would bypass the intractable issues related to H_2 storage and delivery, since NH_3 has a high hydrogen storage capacity of 17.6 wt.% and can be easily stored and transported in liquid form under mild conditions. NH_3 decomposes to H_2 , which produces only H_2O after combustion, and N_2 , which is not a greenhouse gas; in other words, NH_3 is a CO_x -free H_2 carrier. Another class of a hydrogen carrier is an organic hydride such as cyclohexane (CH) and methylcyclohexane (MCH). In dehydrogenation reaction, CH and MCH reversibly produce benzene (BEN) and toluene (TOL), based on the equilibrium reaction, respectively, while BEN and TOL are re-hydrogenated into CH and MCH, respectively. Methylcyclohexane-toluene-hydrogen (MTH cycle) and cyclohexane-benzene-hydrogen (CBH cycle) need reversible and highly selective conversion to sustainable use. Therefore, the advantages of NH_3 mentioned above make the NH_3 -mediated hydrogen economy extremely attractive and promising. Other H_2 carriers, such as methanol, dimethyl ether, etc., inevitably cause end-user CO_2 emissions, since they are carbonaceous compounds and on-board CO_2 capture is not feasible.

As shown in the following equations, another advantage of NH_3 -energy systems is the low heat of reaction. Approximately 30 kJ is required for one mole of produced H_2 in NH_3 system, which is lower than in MTH cycle (70 kJ) and steam reforming of methane (SRM) (40 kJ).

$$\Delta H = +164.5 \text{ kJ/mol}$$

$$\Delta H = +204.6 \text{ kJ/mol}$$

$$\Delta H = +46 \text{ kJ/mol}$$

Membrane reactors can be categorized based on configuration of catalysts as packed type membrane reactor, fluidized membrane reactor, and catalytic membrane reactor. As shown in Fig. 1, packed bed membrane reactors consist of catalysts for reaction as well as membranes for separation. Both catalyst particles and membranes are packed into one unit, but reaction and separation occur separately. On the other hand, catalytic membranes have catalytic activity as well as separation ability in one membrane. Zeolite membranes such as ZSM-5 and TS-1 are inherently catalytically active, while another type of catalytic membrane is a silica hydrogen separation membrane on catalytically active support which can be prepared using catalytically active powders such as nickel oxides or impregnation of Ni-catalyst inside porous α -alumina supports (Tsuru et al. 2004).

Membrane reactors combining a catalytic reaction with the separation process into a single unit offer an ideal device to produce H_2 from NH_3 efficiently, where enhanced NH_3 conversion and high-purity CO_x -free H_2 can be simultaneously obtained by applying a hydrogen separation membrane. Ru is reported the most active catalyst for ammonia decomposition and is supported on porous carbon such as carbon nanotubes (CNT) with supporting catalysts such as potassium (K). To date, only a few studies have reported membrane reactors for NH_3 decomposition in a packed bed Pd membrane reactor, and improved NH_3 conversion was obtained after H_2 extraction.

Another class of membrane reactor is a catalytic membrane reactor. Figure 2 shows a schematic bimodal catalytic membrane reactor (BCMR) (Li et al. 2013). This new type of membrane reactor had a configuration that consisted of a silica separation layer and a bimodal catalytic support ($\text{Ru}/\gamma\text{-Al}_2\text{O}_3/\alpha\text{-Al}_2\text{O}_3$). The impregnation of $\gamma\text{-Al}_2\text{O}_3$ into an $\alpha\text{-Al}_2\text{O}_3$ membrane support to

Ammonia Decomposition in Catalytic Membrane Reactors, Fig. 1 Configuration of membrane reactors

Ammonia Decomposition in Catalytic Membrane Reactors, Fig. 2 Schematic diagram of the proposed bimodal catalytic membrane reactor for CO_x-free H₂ production via NH₃ decomposition (Li et al. 2013)

Ammonia Decomposition in Catalytic Membrane Reactors, Fig. 3 Bimodal catalytic membrane reactor performance for NH₃ decomposition at 450 °C (Li et al. 2013)

form a bimodal support is expected to effectively improve catalytic membrane reactor performance, since the bimodal structure contains both mesopores and macropores, which results in

improved catalytic activities by mesopores and high gas diffusivity by macropores.

Figure 3 shows an example of enhancement of conversion for the BCMR performance for NH₃

decomposition at 450 °C. During the initial 250 min without sweep gas, a NH₃ conversion was 45 %. When N₂ sweep gas was applied to the permeate stream of the membrane reactor, NH₃ conversion was significantly enhanced from 45 to 95 % after the selective H₂ extraction. NH₃ decomposition rate is strongly inhibited by the presence of H₂, particularly at a high pressure. Therefore, the highly enhanced NH₃ conversion can be ascribed to the improved kinetics from H₂ extraction in the BCMR.

Amorphous Fluoropolymers

Marco Avataneo

RD&T, Solvay Specialty Polymers, Bollate (MI), Italy

Synonyms

Fluorinated polymers; Fluoroplastics; Noncrystalline

Amorphous fluoropolymers are noncrystalline synthetic polymers where the hydrogen atoms of the backbone have been partially or completely replaced by fluorine atoms. While common fluoroplastics are semicrystalline, the number of commercial amorphous perfluoropolymers is relatively limited (Scheirs 2001).

In fluorinated polymers the crystallinity, characteristic of perfluorocarbon –CF₂CF₂– units, can be reduced by incorporation of monomers with pendant side groups, like hexafluoropropene or perfluorovinyl ethers, which disrupt the regularity

of the polymeric sequences and increase the intermolecular distances. The complete suppression of the crystallinity is, instead, more easily achieved by introduction of elevated percentage of cyclic monomeric units; by following this strategy, new families of amorphous glassy perfluoropolymers (Teflon[®] AF, Cytop[®], and Hyflon[®] AD whose structures are reported in Fig. 1) were developed and commercialized starting from the late of 1980s (Merkel et al. 2006).

The cyclic groups, present in each of these three structures, hinder efficient chain packing, thus preventing crystal formation and yielding completely amorphous polymers with a glass transition (T_g) tunable but always sensibly above room temperature (from 95 °C of Hyflon[®] AD40 to 240 °C of Teflon[®] AF2400).

Teflon[®] AF, Cytop[®], and Hyflon[®] AD combine the properties typical of perfluorinated semicrystalline materials (high thermal and chemical resistance, low dielectric constant, low surface energy) with new peculiar properties imparted by the amorphous structure such as the high solubility in fluorinated solvents and excellent transparency across a broad wavelength range (from UV to near IR). Furthermore, the high chain stiffness imparted by the cyclic units leads to a difficult packing of the chain segments with the consequent formation of nano-voids which are responsible for the high gas diffusion of these polymers. Gas separation membranes, pellicles for microlithography, protective coatings, dielectric layers for organic and electronic and plastic optical fibers are the most important applications of these glassy perfluoropolymers.

Other two important families of amorphous fluoropolymers, in this case displaying a T_g value below room temperature, are perfluoropolyethers (PFPEs) and fluorinated elastomers. The former (Fig. 2), obtained by means of different manufacturing technologies (Rizvi Syed 2009; Marchionni et al. 1996), are low molecular weight polymers containing etheric oxygen atoms in the backbone which make the chains extremely flexible so preventing the formation of crystalline phases.

These synthetic fluids display extremely low T_g, even below –100 °C. They find applications

Amorphous**Fluoropolymers,**

Fig. 1 Structure of three commercial amorphous glassy perfluoropolymers

**Amorphous****Fluoropolymers,**

Fig. 2 Structure of the four most important commercial perfluoropolyethers

as lubricants for extreme conditions (high temperatures, high pressure, presence of aggressive chemicals), as testing and heat transfer fluids in electronic, and as inert solvents. PFPEs containing functional-end groups can be used as building blocks for the synthesis of two-phase materials (partially fluorinated, partially hydrogenated), surface treatment agents, and surfactants. Few applications in the field of membranes are known for PFPEs (Chaouk et al. 2001).

Fluorinated elastomers (Moore 2006) are cross-linked amorphous polymers with T_g below room temperature. They are generally obtained by copolymerization of at least two of the following monomers: tetrafluoroethylene, vinylidene fluoride, hexafluoropropene, and perfluorovinyl ethers. Fluorosilicone elastomers, i.e., fluorochemically modified polysiloxanes, are another important class of fluorinated elastomers. Fluoroelastomers show extreme resistance to high temperatures and to a variety of aggressive fluids. They exhibit excellent resistance to oils, solvents, acids, alkalis, and ozone over a wide temperature range (-30°C to 250°C) and, therefore, they are suitable for aggressive environments and severe conditions. No relevant industrial applications in the field of membranes are known.

Amorphous Perfluoropolymers

Marco Avataneo

RD&T, Solvay Specialty Polymers, Bollate (MI), Italy

Synonyms

Fully fluorinated polymers; Noncrystalline

Amorphous perfluoropolymers are noncrystalline fully fluorinated synthetic polymers composed exclusively by carbon, fluorine, and oxygen atoms. The most relevant product family for membrane applications is represented by the glassy amorphous perfluoropolymers containing dioxole groups (Teflon[®] AF, Hyflon[®] AD, and Cytot[®]) which display a glass transition above room temperature (Merckel et al. 2006). Perfluoropolyethers and perfluorinated elastomers are, instead, the two most important families of amorphous perfluoropolymers with a glass transition below room temperatures. Perfluoropolyethers (Marchionni et al. 2006; Sanguineti et al. 1995) are a class of synthetic lubricants characterized by extremely low T_g, also below −100 °C. They find applications as lubricants for extreme conditions (high temperatures, high pressure, presence of aggressive chemicals), as heat transfer fluids and as inert solvent (they are good solvent for the glassy amorphous perfluoropolymers). The commercially available PFPEs include Krytox[®], Fomblin[®], and Demnum[®]. Perfluoroelastomers (Moore 2006), also referred to as FFKM elastomers, are amorphous cross-linked polymers obtained by copolymerization of tetrafluoroethylene with hexafluoropropene and/or perfluorovinyl ethers which effectively disrupts the crystallinity imparted by the TFE segments (Marshall 1997). Perfluoroelastomers are characterized by improved thermo-oxidative stability and oil resistance (compared with VDF-based elastomers) for extreme industrial and military applications. Unlike the glassy amorphous perfluoropolymers, no relevant industrial membrane applications for perfluoropolyethers and for perfluoroelastomers are known.

Amorphous Polymers and the Amorphous Region

Petr Sysel

Department of Polymers, Institute of Chemical Technology, Prague, Czech Republic

Polymers consist of the large molecules (polymer chains). An arrangement of these chains in the bulk polymer is given by their chemical composition, spatial orientation (e.g., an isotactic vs atactic polypropylene), molecular weight, and processing conditions (e.g., a cooling rate). Based on these factors, bulk polymers show an amorphous or partially crystalline (semicrystalline) phase state. In the amorphous state, an ordering of the (entangled) polymer chains is random. The amorphous polymer does not include a long-range order, but it is characterized by the existence of some regularity on a short-range order. As a consequence of it, an

Amorphous Polymers and the Amorphous Region, Fig. 1 Thermomechanical curve of an amorphous polymer

X-ray diffraction provides a diffuse ring only (a set of discrete rings is typical for well-ordered structures). If the amorphous polymer is exposed to a gradually increased temperature, it passes from a glass (hard and rigid) to a rubber (soft and flexible) and finally to a molten consistency. Boundaries between the glass/rubber and rubber/molten consistency are given by a glass transition temperature (T_g) and flow temperature, respectively (see a thermomechanical curve of an amorphous polymer, Fig. 1).

The glass transition temperature of the polymer is also an important indicator of its application temperature region (e.g., polydimethylsiloxane ($T_g = \text{ca } -120^\circ\text{C}$) is rubbery and polystyrene ($T_g = \text{ca } +100^\circ\text{C}$) is a glassy polymer at room temperature). A character of the main backbone (flexible/rigid), its substitution (small vs bulk substituents), and a level of molecular (chain) interactions (e.g., van der Waals forces vs hydrogen bonds) are important factors influencing the position (value) of this transition. A flexibility of the chains (or segments) of an amorphous polymer is restricted at temperatures below its T_g . Under heating, molecular interactions (secondary forces) are disrupted, and a free volume among more flexible chains increases (Fig. 2).

An extent of this (segmental) chain motion and free volume influences a lot of the polymer properties, e.g., a transport of the different low-molecular-weight media through the membranes made of these polymers (Strathmann 2011). For example, a nonporous (dense) membrane made of a rubbery polysiloxane [$-\text{Si}(\text{R})_2-\text{O}-$] $_n$, where R is often CH_3] shows a much higher gas permeation (and also diffusivity) in comparison with those made of common glassy polymers at room temperature (Pandey 2001; Bernardo et al. 2009). But their selectivity is traditionally low (Robeson 2008).

Some polymers (e.g., polyethylene, polyamides) include both amorphous and crystalline fractions, and they are called semicrystalline ones. Chains of such polymers may be organized in spherulites having a well-ordered lamellar structure (i.e., a folded chain) with an incorporated disordered amorphous fraction (Fig. 3).

Amorphous polymers are usually transparent; semicrystalline ones are opaque. A segmental mobility of the amorphous regions in semicrystalline polymers varies from that of the amorphous polymer. These regions are affected by the presence of crystalline phase, and this phenomenon influences also transport characteristics of the

penetrating media. Traditionally, the “more dense” crystalline phase decreases a chain mobility and prolongs a transport trajectory of penetrating media, and – as a consequence of this – their permeability decreases (Pandey 2001). Nevertheless, some exceptions were also found, e.g., an increase of gas permeability in a polylactide membrane with its increasing crystallinity (Colomines et al. 2010).

Amphiphilic Membrane from Amphiphilic Molecules

Amphiphilic membrane is a kind of planar arrays of one or two monomolecular layers, which are derived from self-assembly of amphiphilic molecules, such as lipids, surfactants, or block copolymer amphiphiles, through noncovalent interactions in aqueous solution or in oil–water mixtures (Lipowsky et al. 1992; Lipowsky 1991). Amphiphilic molecules, such as lipids or surfactants, possess a hydrophilic (lipophobic) head and a hydrophobic (lipophilic) tail consisted of one or two hydrocarbon chains. The hydrophilic head prefers to be in contact with water in aqueous solution, whereas the hydrophobic tail tends to minimize contact with water. In aqueous solution or in oil–water mixtures, such molecules can form a variety of structures (assemblies) due to the hydrophobic effect. In many cases, the molecules form amphiphilic membranes consisted of a monomolecular monolayer of amphiphiles. For example, the phospholipid molecules self-assemble vertically as a monolayer film at the interface between water and air, with their hydrophilic head groups immersed in the water and their hydrophobic tails pointed to the air, as shown in Fig. 1a (Costa et al. 2012). The two-dimensional membrane also can be observed in the lamellar aggregates of surfactant molecules at the oil–water interface in a microemulsion. These two-dimensional monomolecular insoluble membranes formed by spreading amphiphilic molecules on the surface of a liquid are also referred to as Langmuir monolayers (Kaganer et al. 1999; Dücks and Schmid 2001). These one-molecule-thick films display many advantages compared to the other model membranes, which are excellent model systems for studying chemical and biological reactions in two dimensions, dynamic adsorptions and interfacial behaviors, as well as membrane hydrolysis processes (Dynarowicz-Łatka et al. 2001). These monolayers also provide a way to manipulate molecules and construct artificial materials for optical, electronic, or sensor applications (Kaganer et al. 1999).

Amphiphilic molecules dissolved in water at appropriate concentrations can also self-assemble into bilayer structures with a thickness of only a

few nanometers, as shown in Fig. 1a. Such bilayer membranes consist of two opposing layers of amphiphiles. The hydrophilic heads are oriented towards the surrounding water, while the hydrophobic tails overlapped and packed the middle of the membrane (Lipowsky et al. 1992; Lipowsky 1991). The bilayer membranes are usually found either in the form of closed vesicles or as part of a multilayer stack of lamellae (Chowdhury and Stauffer 1991; Leibler and Andelman 1987). Particularly, lipid bilayers are one of most important amphiphilic membranes due to their properties and their importance in biological systems. The lipid bilayers are a general structure of cell membrane of almost all living organisms, forming the barrier between cytosol and extracellular environment. Many biological functions and cellular processes for cell-surface recognition, signaling, and transport are performed at such biological interfaces (Shillcock and Lipowsky 2002; Han et al. 2013). The importance of the lipid bilayers have aroused great interest in fabricating artificial bilayer membranes, including both freestanding lipid membranes and solid-supported membranes. These bilayer membranes are popular models of cell membranes, which

have universal application in biology and nanotechnology, such as ion channel activity, lipid phase separation, charged lipids manipulation, cell signaling, cell-cell interaction, membrane base biosensor, and protein binding (Han et al. 2013).

Amphiphilic membranes prepared from the self-assembly of lipids have a certain amount of fluidity, depending crucially on the temperature as well as chain structures and physicochemical properties of amphiphiles. Therefore, their permeability, stability, and mechanical characteristics are not particularly well controlled (Illya et al. 2005; Discher et al. 1999; Discher and Eisenberg 2002). Like natural phospholipids, amphiphilic block copolymers in water can also self-assemble into various ordered lamellar structures. The morphology of the resultant nanostructures was controlled by many factors. The volume ratio of the hydrophilic to hydrophobic block of membrane-forming amphiphiles was proposed to be one of the most important parameters in the self-assembly process. Bilayer membranes, as shown in Fig. 1b, can be formed if the hydrophilic/hydrophobic length ratio is sufficiently small (i.e., the critical aggregation

Amphiphilic Membrane, Fig. 2 Amphiphilic membranes based on amphiphilic polymer conetworks. (a) Typical structures of segmented amphiphilic polymer conetworks. (b) A typical synthesis method of amphiphilic polymer conetworks. (c) Amphiphilic membranes

concentrations approach zero) (Battaglia and Ryan 2005; Du and O'Reilly 2009). Moreover, the lamellar structures of amphiphilic diblock copolymers are often thermodynamically unstable, which tend to close to form a hollow structure, i.e., polymer vesicles or polymersomes (Fig. 1c). Compared to lipid-based vesicles, the stiffness and stability of polymersomes are higher because of the length and conformational freedom of polymer chains, which made polymersomes have potential for more applications in materials science, biology, and biomedical science (Battaglia and Ryan 2005; Du and O'Reilly 2009).

Amphiphilic Membrane Based on Amphiphilic Conetworks

The term “amphiphilic membrane” also refers to a polymeric membrane based on amphiphilic conetworks (Fig. 2a), which consist of hydrophilic and hydrophobic chain segments covalently bonded to each other. The cocontinuous interconnected hydrophilic/hydrophobic phases

response to hydrophobic and hydrophilic solvents. The schematic illustrations were made according to the references (Patrickios and Georgiou 2003; Erdodi and Kennedy 2006 with permission from Elsevier)

make amphiphilic conetworks exhibit amphiphilic characters (Isayeva and Kennedy 2004; Bruns et al. 2005; Erdodi and Kennedy 2006). They commonly can be synthesized by a multistep condensation (Fig. 2b) or a free-radical copolymerization with simultaneous cross-linking (Erdodi and Kennedy 2006; Patrickios and Georgiou 2003). As shown in Fig. 2c, such networks can swell in both aqueous and organic media without losing their dimensional stability and without encountering macroscopic phase separation or polymer leaching, which have a great potential for applications such as contact lenses, pervaporation membranes, and drug delivery systems (Erdodi and Kennedy 2006; Patrickios and Georgiou 2003; Isayeva and Kennedy 2004).

Amphipathic molecules; Amphiphiles; Amphiphilic block copolymers; Amphiphilic polymers; Amphipols; Detergents; Emulsifiers; Hydrotropes; Lipids/phospholipids; Soaps; Surfactants

Amphiphilic molecules is a general term that describes any compound that contains two distinct covalently bonded components with different affinity for the solvent in the same molecule, in which one part possesses a high affinity for polar solvents (such as water), and another part has a strong affinity for nonpolar solvents, such as hydrocarbons, ethers, and esters. Surfactants, polymer amphiphiles, and some lipid molecules, containing both hydrophilic and hydrophobic components, are typical examples of amphiphilic molecules.

Low Molecular Weight Amphiphiles

Surfactants (surface active agents), more popularly known as soaps, are among the oldest known chemicals used by human. This type of molecules now play a crucial role in many areas

Amphiphilic Molecules, Fig. 1 Schematic illustrations of surfactants and corresponding assemblies. (a) Structures of surfactants, (b) Surfactant assemblies and the effect of the packing parameter (p). $p = v/(a_0 l_c)$, determining the assemblies' morphologies, where v is the volume of the hydrophobic segment, a_0 is the contact area of the polar head group, and l_c is the length of the hydrophobic

segment. When $p < 1/3$, spheres are formed; when $1/3 < p < 1/2$, cylinders will be favored; when $1/2 < p < 1$, flexible lamellae or vesicles are produced; finally, when $p = 1$, planar lamellae are obtained. If $p > 1$, reversed structures can be observed (The schematic illustrations were made according to the Zhang et al. (2012) with permission from Elsevier)

such as cleaning products, food, cosmetics, pharmaceuticals, and oilfield chemicals as well as biological processes (Holmberg et al. 2002; Schramm et al. 2003; Chevalier 2002). Generally speaking, surfactants possess a hydrophilic head which might be either charged or uncharged and a hydrophobic tail composed of one or more hydrocarbon, fluorocarbon, or dimethylsiloxane chains (Fig. 1a). According to the nature of their polar head group, these molecules can be typically classified into four categories (Fig. 1a): (1) cationic surfactants containing a positively charged head group (e.g., fatty amine salts and quaternary ammoniums); (2) anionic surfactants with a negatively charged head group such as carboxylate, sulfate, sulfonate, or phosphate; (3) nonionic surfactants with an oligo(ethylene glycol) chain as hydrophile; and (4) Zwitterionic surfactants comprised of a long hydrocarbon chain and a hydrophile containing both positive and negative charges. Some new surfactants such as bolaamphiphiles and Gemini surfactants have

attracted much attention because of greater surface activity (Chevalier 2002; Fuhrhop and Wang 2004). Owing to their special structures and amphiphilic properties, surfactants can reduce the surface tension when adsorbing at air–water or oil–water interface at very low concentration, which can offer a number of surface chemistry functions, such as solubilizing, wetting, emulsifying, foaming, and surface conditioning (Holmberg et al. 2002; Schramm et al. 2003). More importantly, these amphiphilic molecules can spontaneously segregate and self-assemble into a wide variety of nanostructures through solvophobic interactions, when the concentration of amphiphiles is above a certain critical concentration (i.e., the critical micelle concentration, CMC, defined as the concentration of surfactants above which micelles are spontaneously formed) (Holmberg et al. 2002). The morphologies, including spherical micelles, cylindrical micelles, lamellae, vesicles, etc. (Fig. 1b), are governed by the molecular structure of the surfactants as well

Amphiphilic Molecules, Fig. 2 Schematic illustrations of typical chain structures (a) and morphologies of amphiphilic polymers in solution (b) and in bulk (c) (The

schematic illustrations were made according to the Wang and Grayson (2012), Mai and Eisenberg (2012) with permission from Elsevier and The Royal Society of Chemistry)

as by physical parameters such as concentration, temperature, and ionic strength. The size and shape of the aggregates were often predicted by using the packing parameter (p), which is the ratio of area occupied by the hydrophilic head and hydrophobic groups of amphiphiles (Israelachvili et al. 1976). The properties and performances of surfactants are closely related to their self-assembly behaviors, and thus it still requires much deeper understanding on the relationship among the molecular structures, aggregation behaviors, and application properties of these amphiphiles.

Macromolecular Amphiphiles

Amphiphilic polymers are another kind of typical amphiphilic molecules of high molecular weight

(Holmberg et al. 2002; Nagarajan 2011). Due to the coexistence of both hydrophobic and hydrophilic moieties on the same molecule, they are also able to self-assemble into a number of nanostructures in solution (Fig. 2b) and in bulk (Fig. 2c), which are analogous to those aggregates of the small-molecule amphiphiles. Moreover, their self-assembly behaviors follow the same principle as that of surfactants (Mai and Eisenberg 2012), and thus at least to some degree, the morphologies of polymer assemblies can also be predicted by the dimensionless p , as shown in Fig. 2b. In addition, the hydrophilic/hydrophobic ratio, copolymer concentration, solvent properties, etc. can significantly affect the morphologies of the final nanostructures (Mai and Eisenberg 2012). Due to the great versatility of polymers in terms of their molecular weight, chain architecture, polydispersity, and reactivity as well as

synthetic diversity, amphiphilic polymers can provide greater opportunities for flexibility, diversity, and functionality. This is especially true in the light of recent advances in controlled/living radical polymerization chemistry, such as ATRP and RAFT polymerization, for the preparation of polymers of various architectures, including linear block copolymers, graft copolymers, dendritic polymers, star-like polymers, and cyclic polymers, as shown in Fig. 2a. Under certain conditions, all of these types of amphiphilic polymers can also self-organize into aggregates of diverse morphologies (Mai and Eisenberg 2012; Wang and Grayson 2012). In addition, the size, morphology, and function of the resulting polymeric assemblies can be easily controlled by adjusting the structure of the amphiphilic copolymers. Compared to small-molecule aggregates, polymer aggregates exhibit higher stability and durability (Mai and Eisenberg 2012). Particularly, stimuli-sensitive polymer assemblies that can respond to subtle changes in surrounding environment such as pH, temperature, and solvent quality can be feasibly realized via the self-assembly of polymer amphiphiles with responsive groups (Schacher et al. 2012; Zhang et al. 2012). Therefore, it is no wonder that amphiphilic polymers and their assemblies have attracted considerable attention and achieved significant success in many fields, such as biomedicine, biomaterials, pharmaceuticals, microelectronics, and photoelectric materials.

Amphoteric Ion Exchange Membrane

Tongwen Xu

Collaborative Innovation Centre of Chemistry for Energy Materials, School of Chemistry and Material Science, University of Science and Technology of China, Hefei, China

Amphoteric ion exchange membrane is a kind of membrane containing random arrangements of both cation and anion exchange groups. When firstly proposed by Söllner in 1932 (Söllner 1932), amphoteric ion exchange membranes mainly refer to membranes having a combination of weak acidic (cation exchange) and weak basic (anion exchange) groups. Nowadays, they are expanded to include membranes containing a combination of weak acidic (or weak basic) with strong basic (or acidic) functionalities or a combination of strong acidic and basic groups. Basically, there are four types (Sata 2004): (1) membranes in which both anion and cation exchange groups are distributed at random during the preparation procedures, such as copolymerization, (2) snake cage-type amphoteric membranes, (3) polysalt membranes, and (4) membranes prepared by a “layer-by-layer” method. The amphoteric ion exchange membranes can show superior antifouling properties, peculiar selectivity, and permeability and hence are useful in the biomedical and industrial fields, such as medical devices (e.g., hemodialysis membrane), separation of ionic drugs and proteins, and depletion of electrolytes by nanofiltration or piezodialysis as well as high performance gel actuator. Membrane having properly combined anion and cation exchange groups shows selective permeability for inorganic salts and, therefore, is able to separate a low molecular organic substance from an inorganic salt, acid, or alkali as well as salt from acid or salt from alkali (Eguchi et al. 1981).

Amphoteric Ion Exchange Membrane, Fig. 1 Transport number of hydrogen ions relative to sodium ions (P_{Na}^H) and current efficiency of cations to the composition of amphoteric ion exchange membranes. (O, ●): quaternized membranes (N-methyl pyridinium and sulfonic acid groups); (Δ, ▲): tertiary amino groups membrane; (pyridinium hydrochloride and sulfonic acid groups); (●, ▲): P_{Na}^H ; (O, Δ): current efficiency (%). Electrodialysis was carried out at a current density of 20 mA cm^{-2} using a mixed solution of 0.25 N sodium chloride and 0.25 N hydrochloric acid for 60 min at 25.0°C (Yamane et al. 1965)

Meanwhile, some of the membranes have compositions that show hydrogen ion permselectivity relative to sodium ions in electrodialysis (Yamane et al. 1965) (Fig. 1).

Analytical Pervaporation

Wanqin Jin

State Key Laboratory of Materials-Oriented
Chemical Engineering, Nanjing University of
Technology, Nanjing, China

The relatively new developed pervaporation in analytical chemistry is in principle a separation technique for the removal of volatile analytes or their volatile derivatives from the sample matrix. Also, it can be used for sample pretreatment, e.g., for solid samples where leaching and derivatization of the analytes are done simultaneously. Analytical pervaporation can be defined as the integration of evaporation and gas diffusion in a single module. Through a porous membrane, the volatile substances present in a heated donor phase evaporate. And on the other side of the membrane, the vapor condenses on the surface of a cool acceptor stream. The driving force for the separation is due to the temperature difference, which leads to a vapor pressure difference across the membrane. For analytical pervaporation, an important feature is that the existence of a constant-volume air gap between the sample in the donor chamber and the membrane, which hinders any contact between them. As a result, the clogging and/or deterioration of the membrane can be avoided (Luque de Castro 1998).

The conventional version of the analytical pervaporation module is shown in Fig. 1 and consists of the following parts: (i) a lower donor chamber (DC) in which the sample containing the analyte is introduced, either by injection or by continuous aspiration for liquid samples and by direct weighing for solid samples, (ii) an upper acceptor chamber (AC) in which an appropriate fluid is circulated for receiving the pervaporated analytes, (iii) a membrane support (MS) approximately 1 mm thick, and (iv) spacers of varying thickness (between 2 and 10 mm) which can be placed above or below the membrane support in

Analytical Pervaporation, Fig. 1 Conventional pervaporation module. DC donor chamber, AC acceptor chamber, MS membrane support, *m* membrane, AG air gap, AS aluminum supports, DI, DO inlet/outlet of donor stream, respectively, AI, AO inlet/outlet of acceptor stream, respectively

order to increase the volume of the corresponding chamber. The different parts of the module are aligned by inserting metallic rods into four orifices and a closer contact is achieved by screwing them between two aluminum supports (AS). The whole module is normally made of methacrylate, which permits continuous monitoring of the sample level in the lower chamber during the experiments Luque de Castro and Papaefstathiou (1998).

Constantly being hydrophobic, the membranes for analytical pervaporation are usually employed in ultrafiltration and gas-diffusion processes. Practically, polytetrafluoroethylene (PTFE) is the most frequently used membrane material, followed by hydrophobic polyvinylidene fluoride (PVDF) Luque de Castro and Gdmiz-Gracia (2000). In combination with the large surface area of both the donor and acceptor chambers, the ultrafiltration membranes, which are very thin, lead to their easy bending. In result, the flux of the permeating component changes through an altered membrane area, and therefore, it leads to a change in the efficiency of the process in addition to reproducibility problems; consequently, the membranes must be changed quite often. Due to their thickness, gas-diffusion membranes are not so easily bent, so the same membrane can be used

over longer periods. The efficiency of the process is influenced by the pore size of the membrane (or its directly proportional thickness) and hence the sensitivity of the method; it affords application to samples with variable analyte concentrations, as a result.

Analytical pervaporation can be used for the determination of a single analyte or a number of analytes, being of inorganic, organic, or organo-metallic nature. Application of analytical pervaporation in the environmental field has been reported especially for food analysis Amador and Luque de Castro (2000). which is the analytical field in which pervaporation has been most widely applied. Other fields of application of pervaporation have been pharmaceutical and clinical analyses.

Anion-Exchange Membrane (AEM)

Mitsuru Higa
Graduate School of Science and Engineering,
Yamaguchi University, Ube, Yamaguchi, Japan

The **anion-exchange membrane (AEM)** is a thin film with anion-exchange groups (positively charged groups) and permeates anions selectively. AEMs are classified according to the species of the ion-exchange groups and materials constituting the membrane and microstructure.

Anion-exchange groups are positively charged groups: primary, secondary, and tertiary amino groups, quaternary ammonium groups, tertiary sulfonium groups, quaternary phosphonium groups, cobalticinium groups, and other groups that provide a positive fixed charge in aqueous or mixed water and organic solvent solutions. Based on the materials constituting membranes, AEMs can be classified as (i) organic membranes, (ii) inorganic membranes, and (iii) composite membranes of inorganic ion exchangers and organic polymers. AEMs are also classified into two types by their microstructure: heterogeneous and homogeneous. Heterogeneous AEMs consist of finely powdered anion exchanger and an inert binder polymer. Various methods have been reported for preparing homogeneous AEMs. A typical example of a hydrocarbon AEMs is a copolymer membrane composed of styrene and divinylbenzene with benzyltrimethylammonium groups. These membranes will be prepared, for example, by the reaction of trimethylamine with a copolymer membrane prepared from chloromethylstyrene and divinylbenzene or by alkylation with alkyl halide of a copolymer membrane prepared from vinylpyridine and divinylbenzene.

Though AEMs have been used in many fields, most are used in electrodialysis, separation of electrolysis, and solid polymer electrolytes for fuel cells. The properties required depend on the intended application of AEMs. Generally required properties are (1) low electrical resistance, (2) high transport number of anions, (3) low diffusion coefficient of electrolytes, (4) low osmotic water and low electroosmotic water, (5) antifouling properties, (6) mechanical strength, (7) dimensional stability, (8) high chemical stability and durability, and (9) low cost (Sata 2004).

AEMs with low sulfate ion permeability have been industrially used to prevent precipitation of calcium sulfate in the AEMs and electrodialyzer. A nitrate ion permselective AEM has been developed and has contributed to human health because the concentrations of nitrate ions are greatly increased in groundwater. To prepare these

functionalized AEMs, ordinary AEMs are modified by suitable chemical or physical methods. For example, most commercially available homogeneous AEMs are mainly cross-linked with divinylbenzene. When the contents of divinylbenzene increase or compact layers are formed on the AEMs, the pore size of the membrane decreases and the transport number of sulfate ions, which are bulky relative to chloride ions, decreases.

Fouling of separation membranes is a common problem. AEMs are fouled by ionic materials of medium molecular weight such as ionic surfactants having the charge opposite to the fixed charged of the membrane. Almost all of organic foulants in many effluent streams have negative charges; hence, fouling of AEMs due to deposition and/or adsorption of the foulants on/in the AEM is one of the serious problems in their applications. The pore size of the AEM is generally recognized to be about 1 nm; therefore, ions of medium molecular weight permeate with difficulty through the membrane. Consequently, the fouling can lead to an unacceptably high stack resistance and replacement of membranes in an electrodialysis system due to clogging of the membrane pores with the medium molecular weight ions. To alleviate the problem of organic fouling, there are basically two methods on the membrane side: first, to increase the pore size of the membrane to allow easy permeation of large ionic materials and, second, to prevent penetration of the materials into the membrane at the membrane surfaces. There are two methods to prevent penetration of large organic materials into the membrane matrix: forming a thin charged layer opposite in sign to the ion-exchange groups of the membrane or forming a very thin and dense layer on the membrane surfaces.

Anion-Exchange Resin

Tongwen Xu

Collaborative Innovation Centre of Chemistry for Energy Materials, School of Chemistry and Material Science, University of Science and Technology of China, Hefei, China

Anion-exchange resin contains positively charged groups, such as $-\text{NH}_3^+$, $-\text{NRH}_2^+$, $-\text{NR}_2\text{H}^+$, $-\text{NR}_3^+$, $-\text{PR}_3^+$, $-\text{SR}_2^+$, etc., which are fixed to the membrane backbone and allow the exchange of anions but repulse cations. As shown in Fig. 1, the active groups existed in the body of resin determine its chemical behavior. It has a highly developed structure of pores on the surface, which could easily trap and release ions.

There are two main types of anion-exchange resins differing in their active groups: strongly basic and weakly basic. (1) Strongly basic resins are highly ionized, and their chemical behavior is similar to that of a strong base which can be used over the entire pH range. They can react with anions in solution and convert an acid solution to pure water. The exhausted resin can be regenerated with concentrated sodium hydroxide (NaOH) and converted to the hydroxide form. (2) The degree of ionization of weakly basic resin is strongly influenced by pH because it is like a weak base. The weak base resin does not have a hydroxide ion form as does the strong base resin. Consequently, its regeneration needs only to neutralize the absorbed acid and does not need to provide hydroxide ions. Less expensive weakly basic reagents such as ammonia (NH_3) or sodium carbonate can be employed.

The selectivity of a resin for a given ion is measured by the selectivity coefficient (K), as for the reaction

The K can be expressed as $K = (\text{concentration of } \text{B}^- \text{ in resin} / \text{concentration of } \text{A}^- \text{ in resin}) \times$

Anion-Exchange Resin,**Fig. 1** Diagram of anion-exchange resin

(concentration of A^- in solution/concentration of B^- in solution).

In general, introducing ionic groups could start with a monomer containing a moiety, a polymer film, or start with polymers or polymer blends (Helfferich 1962; Strathmann 2004). As summarized in our recent book chapter, the specific implementation methods include (1) amidoalkylation of cross-linking polystyrene, (2) copolymerization of (chloromethyl) styrene, (3) chloroacetylation of polymers, (4) acetylation of cross-linked polystyrene, and (5) grafting vinylbenzyl ammonium chloride onto inert polymers (Xu 2009).

Annealing of Polymer Membranes

Maria Luisa Di Vona
 Dip. Di Scienze Technologie Chimiche,
 University of Rome Tor Vergata, Rome, Italy

Annealing can be defined as a process where a material undergoes a heat treatment to a certain temperature, is kept there for a definite time, and is

then cooled to room temperature in order to alter the material properties. The annealing process is time and temperature dependent.

Annealing of polymers is a heating of a polymeric part to below its glass transition temperature in order to relieve the internal stresses introduced during its fabrication (molding, cooling after molding, machining, welding, etc.).

Annealing of conjugated polymers and polymer blend films is a widely used process that achieves optimal film morphology and therefore improves material properties, such as electrical mobility for photovoltaic devices and other applications. Annealing of ion-conducting polymers reduces the excessive swelling observed in presence of water.

In particular, annealing is used (Young and Lovell 1991):

- To increase the melting point of some polymers because it facilitates the melting of small and irregular crystals in favor of larger and better formed ones
- To reduce or cancel deformations previously provoked at higher temperature which remain as frozen (permanent) deformations when the material is cooled to room temperature
- To increase crystallization
- To decrease the free volume between polymeric chains thus inducing a mechanical stabilization of polymeric materials

Annealing of liquid crystalline polymers between the glass transition temperature and the

melting temperature leads to an increased level of crystallinity and increased crystalline perfection analogous to the behavior of conventional semicrystalline polymers. Annealing at or above the melting point also leads to enhanced crystallinity and crystalline perfection.

The annealing of semicrystalline polymers may change the crystal structure, the degree of crystallinity, the perfection of the crystals, the orientation of both crystalline and amorphous phases, their contiguous structural morphology, and the number of tie chains between the crystallites. Morphological changes are also observed on annealing bulk-crystallized samples. Polymorphism may result due to annealing crystalline polymers as its one crystalline form transforms into another. The concept that mechanical stabilization was due to a generic decrease of the free volume between ionomer chains when thermally treated was abandoned and replaced by the consideration that the mechanical stabilization was induced by an increased crystallization of a preexisting semicrystalline phase (Alberti et al. 2013).

Thermal annealing is a simple route for stabilizing glassy polymers via the densification of their polymer chains and is accomplished through thermal treatment of the glassy thermoplastics. For amorphous polymers, the thermal treatment can play a very important role in changing the morphology. If the temperature is lower than the glass transition temperature T_g , the polymer chains are mainly immobile, thereby maintaining the existing morphology; however, if the annealing temperature is greater than the T_g , the polymer chains will relax. It has been found that the morphology can be modified upon annealing at a temperature higher than the T_g , thus changing the physical properties of the polymers.

A certain amount of molecular rearrangement must take place during crystallization but this rearrangement cannot arise through large-scale molecular diffusion as the process is occurring in the solid state. Thermal treatments were believed to be more and more efficient as the temperature increases and therefore empirical short treatments were performed at high temperatures. Thus, the annealing temperature (T_{ann}) was connected with

the crystallization temperature (T_c) and it became clear that the annealing temperature cannot be higher than the melting temperature (T_m) of the semicrystalline phase.

Antibiological Fouling Surface

François Perreault

School of Sustainable Engineering and the Built Environment, Arizona State University, Tempe, AZ, USA

Antibiological fouling surface is a surface having the property to resist the attachment or proliferation of living organisms. In membrane systems, the main organisms of concern for biological fouling are microorganisms. Antibiological fouling membranes may resist biological fouling, or biofouling, by three main mechanisms: reducing the attachment of microorganisms to the surface, killing the microorganisms to prevent their multiplication, or inhibiting their proliferation on the membrane surface (De Kwaadsteniet et al. 2011).

Biological fouling can be reduced by reducing the adhesion of microorganisms and biological foulants to the membrane. Adhesion of foulants on a membrane depends on the physicochemical properties of the surface and is increased with higher surface roughness, hydrophobicity, and electrostatic charge. Surface roughness increases fouling by increasing the contact area between the cell and the surface (Vrijenhoek et al. 2001). Strategies to reduce the surface roughness include changes in the fabrication procedure or filling

the valleys of the surface with polymers or nanomaterials (Rana and Matsuura 2010). Hydrophobic surfaces increase fouling due to the hydrophobic nature of most biological foulants. Increase in the hydrophilicity of a surface generates a hydrated layer that reduces the adhesion of hydrophobic proteins and microorganisms. To achieve a more hydrophilic surface, the membrane may be coated or functionalized with hydrophilic polymers and nanomaterials or chemically modified by treating the membrane with plasma, UV light, different acids or bases, and oxidizing agents (Rana and Matsuura 2010). Electrostatic interactions may increase the adhesion of microorganisms on the membrane. Proteins and microbial cells are generally negatively charged in natural pH. Therefore, lowering the surface charge may decrease foulant adhesion by increasing the electrostatic repulsion. The surface charge of a membrane can be modified by changing the nature of the functional groups present on the membrane surface (Rana and Matsuura 2010). Finally, adhesion of biological foulants and microorganisms may be decreased by surface modification with polymer brushes. The use of long-chain molecules such as polyethylene glycol increases steric repulsion between foulants and the membrane surface (Banerjee et al. 2011). The antifouling effectiveness of the polymer brushes depends on the length and density of the polymer layer.

Biological fouling can be reduced by inactivating microorganisms in order to prevent their development on the membrane surface. Antimicrobial compounds can be integrated in a membrane by including them in the polymer solution during membrane fabrication or by post-fabrication membrane functionalization. These antimicrobial compounds may be biocide-releasing materials, contact-action antimicrobial agents, or photocatalytic materials (Banerjee et al. 2011).

Biological fouling may be reduced by preventing the development of microbial communities without directly killing the microorganisms. This is accomplished by using bacteriostatic or quorum-sensing inhibitors that prevent the assembly of deposited microorganisms into a biofilm.

Such compounds can be directly attached to the membrane or included in a slow-release platform such as polymeric particle (Glinel et al. 2012).

Antibiotic Production by Membrane Operations

Cristiana Boi

Dipartimento di Ingegneria Civile, Chimica, Ambientale e dei Materiali, Università di Bologna, Bologna, Italy

Synonyms

Membranes in antibiotic production

Antibiotics are medicines produced by fermentation that fight bacterial infections; they can either kill other microorganisms or inhibit their growth.

The development of antibiotics started with the discovery of penicillin by Fleming in 1928 that gave rise to many other discoveries in the subsequent 40 years. The number of new antibiotics on the market had a steady increase until the 1980s, but the unrestrained use of antibiotics led to the emergence of antibiotic-resistant pathogens and the number of approved antibiotics decreased constantly in the last 30 years (Coates

et al. 2011). The research for therapeutics endowed with a broaden antimicrobial range brought to the development of semisynthetic antibiotics which are produced by chemical or enzymatic transformation of penicillin and cephalosporins (Srirangan et al. 2013). Penicillin is still one of the antibiotics with the largest annual bulk production; it is part of the β -lactam antibiotic class, with about 15 billion US\$ annual sales and a market share of about 65 % of the total world antibiotic market (Elander 2003).

The production of antibiotics typically involves a series of process steps consisting of fermentation, removal of biomass, purification, and crystallization (Koltuniewicz 2010). Membrane operations can be integrated within this process sequence, both in the upstream and in the downstream processing, for production of either natural or semisynthetic antibiotics.

In upstream processing, membranes are utilized for ancillary operations and, in particular, for sterile filtration of culture media and air which is supplied as a source of oxygen for aerobic fermentation, whereas in the downstream part of the process, they can be utilized as alternative unit operations. In the downstream section, membranes can be applied for cell harvest, clarification, and concentration. Among the membrane technologies used for recovery and purification, crossflow microfiltration and ultrafiltration can be employed for biomass separation, often in combination with diafiltration to improve product yield and purity (Lipnizki 2010).

Antibiotic recovery from fermentation broths can be done directly if the product is extracellular, as in penicillin production, or following cell disruption if the product is intracellular, as for some tetracyclines. Since antibiotics are relatively small molecules, with molecular weights of less than 2,000 amu, the MF/UF membrane retains the biomass or the cell debris when the antibiotic is an intracellular products, while the antibiotics are found in the permeate side. The clarified antibiotic stream can then be concentrated with nanofiltration and/or reverse osmosis (Lipnizki 2010). Purification of antibiotics is generally carried out with solvent extraction, but depending on the target molecule, absorption or precipitation

may also be used. The introduction of an ultrafiltration step greatly improves the extraction process (Koltuniewicz 2010).

Other membrane technologies like membrane contactors, liquid membranes, and membrane bioreactors are less established; however, they have great potential for industrial applications in antibiotic production.

Antifouling Membrane Surface

Zhongyi Jiang¹, Jinming Peng², Xueting Zhao¹, Yanlei Su¹ and Hong Wu¹

¹School of Chemical Engineering and Technology, Tianjin University, Nankai, Tianjin, China

²Key Laboratory for Green Chemical Technology of Ministry of Education, School of Chemical Engineering and Technology, Tianjin University, Tianjin, China

The term fouling generally refers to an undesirable process in which a surface becomes encrusted due to the undesirable accumulation of foulants, such as biomacromolecules,

microorganisms, hydrocarbons, particles, and colloids from the surrounding environment. Antifouling surface, also referred to as a “stealth surface,” can minimize the intermolecular forces of interactions between the foulants and the synthetic surface so that the foulants can be easily released under low shear stresses. Antifouling surfaces lie at the heart of several contemporary and advanced technologies, ranging from coatings for ship hulls, biomedical implants, biosensors, drug delivery, and membrane separations. Antifouling membrane surface is one kind of antifouling surfaces. The antifouling surface is often relevant to membranes utilized in microfiltration, ultrafiltration, nanofiltration, and reverse osmosis. The major foulants are different for different membrane processes. The main foulants are microorganisms and emulsified oils for microfiltration, biomacromolecules and colloids for ultrafiltration, natural organic matters for nanofiltration, inorganic salts and bioorganic/organic substances for reverse osmosis.

All the strategies for construction of antifouling membrane surface are based on manipulating the physicochemical and/or topography structure of membrane surface to weaken the interactions between foulants and membrane surface and thus inhibiting foulants adsorption or settlement. There are four major types of antifouling membrane surfaces, including hydrophilic surface, hydrophobic surface, amphiphilic surface, and reactive surface. Whitesides (Ostuni et al. 2001) first proposed that antifouling surface showing resistance to protein should have the following four attributes: hydrophilic, hydrogen-bond acceptors but not hydrogen-bond donors, and overall electrically neutral. Poly(ethylene glycol) (PEG)-based polymers and zwitterionic polymers are the most widely used materials to fabricate antifouling membranes. The antifouling mechanism of the PEG-based polymers can be mainly ascribed to the large repulsive hydration forces of tightly bound water layer around the polymer chains via hydrogen bonds or electrostatic attraction. The objective of hydrophilic surface is to prevent the foulants from attaching onto the membrane surface, which is known as “fouling resistance”

(Callow and Callow 2011). The hydrophilic membrane surface can resist the fouling caused by biomacromolecules and natural organic matter. The hydrophobic surface is based on nonpolar, low surface energy hydrophobic polymers, such as poly(dimethylsiloxane) (PDMS) elastomers and fluoropolymers. The mechanism of this hydrophobic surface is that polar molecules (including adhesive protein) barely adhere to membrane surface because of reduced opportunities for forming the hydrogen-bonding and polar interactions. This hydrophobic surface aims to weaken the interfacial bonds so that the attached foulants are more readily removed by hydraulic shear forces, not prevent foulants from attaching, which is known as “fouling release.” The hydrophobic membrane surface is suitable for mitigating the microorganism and hydrocarbon fouling. The amphiphilic surface comprising hydrophilic domains and hydrophobic domains on membrane surface incorporates some of the benefits of both hydrophobic and hydrophilic surfaces. The general aim is to create a dynamic and compositional surface complexity that deters settlement of foulants and reduces the interfacial bonding with membrane surface. The general aim of amphiphilic surface is to combine the nonpolar, low surface energy properties of hydrophobic domains to reduce polar and hydrogen-bonding interactions with foulants, with the well-known protein repellency properties of the hydrophilic domains. The resulting amphiphilic surface may lower the entropic and enthalpic driving forces for the adsorption of the protein and organism. The amphiphilic membrane surface can defer the fouling caused by microorganisms, biomacromolecules, natural organic matter, and hydrocarbons. Therefore, the amphiphilic membrane surface is the most promising antifouling membrane surface for the practical separation system containing a wide range of foulants. The reactive surface immobilizes the component which can degrade organic composition of foulants on membrane surface. The proteases and titania nanoparticles are often immobilized on membrane surface, thus preventing biomacromolecules and microorganism fouling via

enzymatic or photocatalytic degradation (Banerjee et al. 2011).

Several modification approaches are employed to create antifouling membrane surface including surface coating, surface grafting, and surface segregation (Shannon et al. 2008; Rana and Matsuura 2010; Wang et al. 2005). For surface coating, membranes are immersed in a polymer modifier solution or inorganic particles suspension. The modifier is settled on membrane surface to create antifouling coating through van der Waals force or electrostatic interactions. For surface grafting, the modifier is settled on membrane surface via graft polymerization including graft-to and graft-from approach. The termed graft-to approaches consist of the grafting of the pre-synthesized polymer chains with a reactive terminal group. Alternatively, graft-from approaches, in which a polymer is grown in situ from the surface via a surface-adsorbed initiation group, are generally capable of producing denser polymer layers. The surface coating and surface grafting belong to the post-modification approach, whereas surface segregation belongs to the in situ modification approach. The polymer modifiers comprising hydrophobic backbones and hydrophilic side chains are added to casting solution, lining membrane surfaces, and internal pore during the conventional phase inversion process. The hydrophilic chains segregate to membrane surface and endow membrane with surface hydrophilicity and antifouling property, while hydrophobic backbones anchor to membrane matrix polymers to defer loss of modifier during phase inversion process.

The fouling resistance property could be evaluated by flux recovery ratio (*FRR*), while the fouling release property could be evaluated by flux decline ratio (*FDR*). The flux recovery ratio (*FRR*) is the ratio of the water flux after hydraulic cleaning to initial water flux, while the flux decline ratio is the ratio of flux decline (the initial water flux minus the flux for real feed) to initial water flux. The higher the value of *FRR*, the better the fouling resistance property of the membrane; the lower the *FDR*, the better the fouling release property of the membranes.

Antimicrobial Activity

François Perreault

School of Sustainable Engineering and the Built Environment, Arizona State University, Tempe, AZ, USA

Antimicrobial activity of a compound is defined as its capacity to prevent the development of microorganisms. Antimicrobial compounds can be divided into two main categories according to their mechanisms of antimicrobial action: bactericidal and bacteriostatic. Bactericidal agents act by killing bacterial cells. Common bactericidal mechanisms include inhibition of cell wall synthesis, disruption of the cytoplasmic membrane, and inhibition of nucleic acid synthesis. Bacteriostatic agents are compounds that prevent microbial development by inhibiting specific metabolic pathways, thus preventing cell growth and multiplication. Bacteriostatic agents act by inhibiting protein synthesis, by acting on the 30S, 50S, or 70S ribosomal complexes, or by inhibiting other

essential metabolic pathways such as folic acid synthesis. Bacteriostatic effect is reversible and bacteria can proliferate once the bacteriostatic agent is removed (McCarter 2005).

Methods to evaluate the antimicrobial activity can be divided into two categories: diffusion methods and dilution methods. Diffusion methods, also called agar diffusion methods, depend on the diffusion of an antimicrobial compound in an agar plate covered by a bacterial lawn. Antimicrobial activity is measured in terms of the diameter of the zone of inhibition, where bacterial growth is inhibited. The most common agar diffusion assay is the Kirby-Bauer assay. Dilution methods aim to determine the minimum inhibitory concentration of a compound, defined as the minimal concentration that completely inhibits microbial growth, by incubating a defined quantity of bacteria with different dilutions of an antimicrobial compound. Dilution methods can be performed in culture broth or in agar media.

In membrane processes, antimicrobial compounds are used to reduce microbial growth and biological membrane fouling. Antimicrobial compounds can be introduced in the feed effluent continuously or intermittently, during membrane cleaning stages, to kill microorganisms and reduce biofilm development (Matin et al. 2011). Traditional approach using chlorine-based disinfectants is usually effective to control biofilm development; however, chlorine disinfection leads to the formation of undesirable and carcinogenic disinfection by-products. Additionally, chlorine is not compatible with polyamide thin-film composite membranes due to the susceptibility of the aromatic polyamide layer to chlorine attack. Alternative strategies to disinfection of the feed effluent include ozone, UV treatments, or advanced oxidation processes, which produce less disinfection by-products but are limited by their higher cost compared to chlorine. Microbial growth and biofilm development may also be reduced by imparting antimicrobial properties directly to the membrane by modification with antimicrobial compounds. Antimicrobial coating of membranes can be achieved using different types of antimicrobial compounds, such as antimicrobial polymers, antimicrobial peptides,

polycations, silver and metal oxide nanoparticles, carbon nanomaterials, biocide-releasing polymeric structures, and photoactive materials (Banerjee et al. 2011).

Antimicrobial Membrane

Jun Yin and Baolin Deng

Department of Civil and Environmental Engineering, University of Missouri-Columbia, Columbia, MO, USA

Antimicrobial membrane (also called antibacterial membrane or anti-biofouling membrane) is a membrane capable of reducing or inhibiting microbial growth on its surface. The biocidal ability of the antimicrobial membrane can generally be exerted by (1) active amphiphilic polymers or synthetic mimics of naturally occurring antibacterial peptides, (2) microbe-repelling anti-adhesive polymers, and (3) composite materials containing various slow-releasing biocides (Sambhy et al. 2006; Yin and Deng 2015).

Why Antimicrobial Membrane Is Important?

Membrane biofouling due to the microbial growth and biofilm formation is one of the most challenging issues in membrane separation for water and

wastewater treatment (Zhu et al. 2010). This undesirable phenomenon decreases membrane permeability, reduces permeate quality, and increases energy consumption of the separation process. It is therefore critical to develop antimicrobial membranes that will most likely increase membrane efficiency and application duration. In addition, use of antimicrobial membrane is important to provide pathogen-free clean water.

Commonly Used Biocidal Agents for Membrane Modification

Biocidal agents that could be used for water treatment include quaternary ammonium compounds (QACs), metal ions or nanoparticles (NPs) such as silver (Ag) and copper (Cu), titanium dioxide (TiO₂), and so on.

QACs possess good antibacterial properties, low toxicity, environmentally friendly performance, and excellent cell membrane penetration properties (Song et al. 2011).

Silver ions/NPs and silver-based compounds have excellent biocidal properties and are widely used to prepare antimicrobial plastics, coatings, and wound and burn dressing, etc. They could inhibit the growth of microbes through multiple pathways. Firstly, released Ag⁺ ions could interact with disulfide or thiol groups of enzymes or DNA and then disrupt microbial metabolic processes, generate reactive oxygen species, or interrupt replication of DNA (Russell and Hugo 1994; Feng et al. 2000; Matsumura et al. 2003), leading to the damage or even the death of bacterial cells. Secondly, Ag NPs can attach to the surface of the cell membrane and disturb its proper function including destabilizing the outer membrane, collapsing the plasma membrane potential, and depleting the levels of intracellular ATP (Sondi and Salopek-Sondi 2004; Lok et al. 2006; Choi et al. 2008). Thirdly, Ag NPs with smaller particle size (1–10 nm) are able to penetrate inside the bacteria and cause further damage by possibly interacting with sulfur- and phosphorus-containing compounds such as DNA (Morones et al. 2005).

Recently, Cu is explored as an alternative of Ag due to its relatively low cost and decent biocidal property. The antimicrobial property of TiO₂ is driven by the photocatalytic reaction, where light irradiation is necessary.

Fabrication and Modification Methods

The antimicrobial functionalization of membranes could be implemented through procedures including blending, surface coating, or grafting. In the blending approach, biocidal agents are mixed with polymer solution during the membrane fabrication. In the coating or grafting approach, biocidal agents are attached onto membrane surface through adsorption, deposition, electrostatic attraction, or chemical bonding. For instance, Ag NPs or Cu NPs could be encapsulated in positively charged polyethylenimine (PEI) and then attached onto a negatively charged membrane surface (Mauter et al. 2011; Ben-Sasson et al. 2014). In order to improve the durability of antimicrobial function, Ag NPs can also be attached onto thin-film composite (TFC) membranes through chemical bonding, resulting in membranes with excellent antimicrobial properties and reduced membrane biofouling (Fig. 1, Yin et al. 2013).

Challenges

Antimicrobial membrane has attracted much attention due to its demonstrated resistance to membrane biofouling. However, several challenges need to be addressed in its practical applications. For long-term application, the loss of antimicrobial activity due to the depletion of biocidal agents or insufficient contact between bacteria and biocide caused by other foulants necessitates frequent recharging and cleaning of membranes. How to attach biocidal agents onto membrane and control their release in a most effective way should be further explored. For commercial applications, there is a need to consider cost-effectiveness of attaching biocidal

Antimicrobial Membrane, Fig. 1 SEM image of membrane surface (1) and TEM image of membrane cross section (2) (Yin et al. 2013)

agents onto a membrane and recharging them as needed.

Antimicrobial Properties of Membranes

Francois Perreault

School of Sustainable Engineering and the Built Environment, Arizona State University, Tempe, AZ, USA

Antimicrobial properties of membrane improve the membrane resistance to biological fouling. Antimicrobial properties can be provided to membranes by modification with different types of antimicrobial compounds, which can be divided into three categories based on their mechanisms of bacterial inactivation: biocide-releasing compounds, contact-action antimicrobial agents, and photocatalytic materials.

Biocide-releasing materials inactivate microorganisms by the release of biocide in the vicinity of the membrane. Common examples of biocide-releasing compounds used for antimicrobial coatings are silver nanoparticles, metal oxide nanoparticles, and polymeric capsules (Banerjee et al. 2011). Biocide-releasing materials may be included in the polymer solutions during fabrication or attached to the membrane via post-fabrication membrane modification. Embedding the biocide in the depth of the membrane may however limit its diffusion to the microorganisms and therefore decrease the antimicrobial activity of the modified membrane (Zodrow et al. 2009). To maximize the effectiveness of biocide release, surface attachment of biocide can be preferred (Mauter et al. 2011). A limitation to biocide-release materials is the eventual depletion of the biocide and loss of antimicrobial activity.

Contact-action antimicrobials are compounds that require direct contact with microorganisms for cell inactivation. Examples of contact-action antimicrobial materials are antimicrobial peptides, enzymes, polycationic polymers, and nanomaterials such as carbon nanomaterials (Banerjee et al. 2011). A common mechanism of cell inactivation by contact-action antimicrobial compounds is the disruption of cell integrity

upon interaction with cell wall components or penetration through the cytoplasmic membrane. This mechanism does not deplete over time and may be effective as long as a direct contact between the cell and the membrane surface is provided.

Photocatalytic materials generate reactive oxygen species upon exposure to visible or ultraviolet light. Their main applications in membrane processes are contaminant degradation and disinfection, where the membrane serves as a support to immobilize photocatalysts. The generation of reactive oxygen species by these materials causes bacterial inactivation by inducing oxidative damage to cell membranes, proteins, and nucleic acids, leading to cell death. Integration of photocatalytic materials into membranes therefore improves the antimicrobial properties of the membrane (Kwak and Kim 2001). Several compounds may be light-activated to generate reactive oxygen species. Among them are dyes like rose bengal, porphyrins, and toluidine blue and particles such as TiO_2 and fullerene (Banerjee et al. 2011). The most common photocatalytic material used in membrane processes is TiO_2 due to its low cost, durability, and self-cleaning properties.

Antioxidant Recovery by Membranes

Laurent Bazinet

Department of Food Sciences, Université Laval,
Quebec, QC, Canada

Antioxidants and Membrane Processes

Antioxidants are natural or synthesized substances that inhibit or retard the oxidation of other molecules (fat, oil, food, petroleum product...) (Focke et al. 2012; Rozoy et al. 2012; Roblet et al. 2012). However, for natural antioxidants, which are present in complex matrices, their separation and purification are required. Indeed, they must be separated from the feedstock in order to increase their purity and antioxidant capacity.

Membrane processes are the main processes used for the separation of antioxidant molecules. Membranes are selective barriers that allow for the transmission of certain feed components while retaining other components. Membrane technology can be used to concentrate and/or selectively fractionate bioactive compounds with antioxidant activity from aqueous and alcoholic processing streams of products, by-products, and wastes from agro-food industry (Diaz-Reinoso et al. 2011). It is important to note that, when compared with other concentration methods (evaporation, spray drying...), during membrane processes the product is not subjected to high temperatures and there is no change in the physical state of the solvent, meaning that the functional properties of the compounds of interest are preserved and the process as a whole is energy saving (Negrao Murakami et al. 2011).

Membrane Processes and Applications to Antioxidant Recovery

On a large production scale, pressure-driven membrane technologies and electrically driven membrane technologies have been developed to

improve the efficiency of antioxidant production (Table 1).

Pressure-Driven Membrane Processes

Pressure-driven membrane technologies are often used in the food industry to isolate antioxidant molecules such as specific peptides or peptide fractions (Bazinet and Firdaus 2012; Pouliot et al. 2000; Tessier et al. 2006a, b; Vandanjon et al. 2009) and phenolic compounds (Nawaz et al. 2006; Kalbasi and Cisneros-Zevallos 2007; Mello et al. 2010; Tylkowski et al. 2010). Pressure is the main driving force for these processes. The pressure used depends on the pore size of the filtration membrane and has to be adjusted as a function of the concentration rate desired. Pressure-driven membrane processes comprise microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO). The solution properties, charges of ionic species and the type of membrane used, affect the behavior and the efficiency of the separation method (Martin-Orue et al. 1998). Working at low concentration is preferable to avoid the formation of a polarization layer which could affect selectivity of the membrane (Shahidi 2004).

For the separation of tocopherols and tocotrienols, only **MF** (de Souza et al. 2008) and **NF** (Subramanian et al. 1998a, b, 2003) were reported. For phenols recovery, **MF** was used on vegetation waters (VW) (Russo 2007) and pineapple juice (Laorko et al. (2010). The authors showed that MF did not affect significantly the pH, reducing sugar and acidity of clarified juice whereas the suspended solids and microorganism were completely removed. **UF** was studied on different sources such as olive mill wastewater (Russo 2007; El-Abbassi 2012), fruit juices (Borneman et al. 2001; Cassano et al. 2008; Laorko et al. 2010; Cissé et al. 2011; Conidi et al. 2011), grape seeds (Nawaz et al. 2006), and green tea (Li et al. 2005). **NF** was tested on roselle extract (Cissé et al. 2011), on mate (Negrao Murakami et al. 2011), on aqueous propolis extract (Mello et al. 2010), and on bergamot juice (Conidi et al. 2011). Organic acids such as Ascorbic, isoascorbic, folic, and citric acids can also be recovered by filtration process. Hence,

MF was used for the recovery of ascorbic acid (Laorko et al. 2010), while **UF** was tested on kiwifruit juice to recover folic, ascorbic, and citric acids (Cassano et al. 2006). Concerning antioxidant peptides, they are separated into fractions using membranes in the range 1–10 kDa (Je et al. 2005; Jeon et al. 1999; Rajapakse et al. 2005). **NF** can be used to concentrate hydrolysates (Vandanjon et al. 2007; Fenton-May et al. 1971; Tessier et al. 2006b) whereas **UF** membranes with high MWCO (20–100 kDa) are adapted to the separation of peptides and nonhydrolyzed proteins or proteolytic enzymes (Bouhallab and Touzé 1995; Lajoie et al. 2001). On the other hand, **UF** membranes with intermediate molecular weight cutoffs (about 4000–8000 Da) allow hydrolysates to be fractionated with the result of enrichment in some ranges

of molecular weight (Vandanjon et al. 2007). The use of integrated membrane system (UF/MF/RO, MF/NF, ...) is becoming another real alternative to recover, purify, or concentrate antioxidants as it is established in some recent works (Paraskeva et al. 2007; Russo 2007; Garcia-Castello et al. 2010; Conidi et al. 2011; Diaz-Reinoso et al. 2011).

Electrically Driven Membrane Processes

Electrically driven processes, like electrodialysis (ED) and hybrid processes (ED with bipolar membranes (EDBM) and ED with filtration membranes (EDFM)), use ion-exchange membranes and/or filtration membrane to separate molecules (Bazinet 2005). The electric field is the main driving force involved in these processes. Molecular transfer is mainly due to the charge of the

molecule and the flux depends on the strength of the electric field (Poulin et al. 2007; Doyen et al. 2012).

Conventional **electrodialysis** has been tested as a mean of selectively extracting polyphenols from aqueous tobacco extracts (Bazinet et al. 2005). High polyphenol migration rates around 31.1–90.8 % were reported. **EDFM** a new electrically driven technology has been recently tested for the recovery of polyphenols. **EDFM** was used on green tea to perform selective extraction of catechins (Labbe et al. 2005) and on cranberry juice to enrich cranberry juice in its own natural phenolic antioxidant compounds (Bazinet et al. 2009, 2012). For organic acids having antioxidant properties, Vera Calle et al. (2003) were indirectly precursor in the use of **ED** for the recovery of citric acid. In all the deacidified juices, a decrease in the citrate and malate concentrations was obtained. Vera Calle et al. (2002) also tested the deacidification of clarified passion fruit juice, by electrodialysis with bipolar membrane (**EDBM**). Citric acid was formed in the concentrate compartment by citrate ions extracted from juice and protons provided by the BM separating the concentrate and electrode compartments. This configuration allowed the production of citric acid with 89 % purity. During **EDFM** of cranberry juice, Bazinet et al. (2012) observed that enriched juice concentrations in citric and malic acids decreased respectively of 7.3 % and 4.7 % resulting in a significant decrease of its sour taste intensity, a major problem for cranberry juice producer. However, the concentration in the raw juice was not significant due to the high ratio of raw juice/enriched juice. Very recently, a combination of UF membrane stacked in an electrodialysis cell was tested successfully for the selective separation of anionic and cationic antioxidant peptides (Langevin et al. 2012). The results showed only a significant increase in the antioxidant capacity for anionic peptide fractions recovered at pH 3 and pH 6 compared to the feed hydrolysate (Langevin et al. 2012). In the comparative study of Langevin et al. (2012), it was demonstrated that **NF** was more efficient in terms of mass flux than **EDFM** when compared on a same basis (membrane area, process duration), but

EDFM recovered larger range of peptide molecular weights and amount of polar amino acids.

Antioxidants Recovery by Integrated Membrane Operations

Alfredo Cassano and Rosalinda Mazzei
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

Natural antioxidants are synthesized by plants, microorganisms, fungi, and animals. They include phenolics, terpenes, proteins, peptides, and carbohydrates. Waste streams from the processing of agricultural feedstocks (residues from grape and wine, apple pomace, peels, woods, olives, seeds, leaves) are particularly attractive as sources of antioxidants.

Antioxidant compounds play an essential role in the human body to reduce oxidative processes. Therefore they offer interesting perspectives and opportunities in the production of dietary supplements and functional foods and potential utilization in pharmaceutical and cosmetic industries. However, since these compounds are generally present in complex matrices, extraction, separation, and purification methods are required in order to improve their purity. Extraction methods ideally should be nondestructive, time efficient, and suitable for producing high quantity of extract

which should be processed by selective techniques able to produce concentrated streams with enhanced antioxidant activity.

The recovery of antioxidants from agricultural by-products can be conducted according to the “5-Stages Universal Recovery Processing” strategy which includes (1) a macroscopic pretreatment, (2) a macro- and micro-molecule separation, (3) an extraction step, (4) an isolation and purification step, and (5) a product formation (Galanakis 2012).

Conventional extraction methodologies are based on the use of resins, organic solvents, enzymes, γ -irradiation, and heat treatment. These methodologies have drawbacks to some degree. For example, the extraction with organic solvents is characterized by safety problems (some of them are believed to be toxic), low efficiency, and time consumption; heat treatment results in pyrolysis; enzymes can be denatured in enzyme-assisted extraction; and γ -irradiation-assisted extraction is still unknown in terms of safety.

Membrane technologies are the main processes used at large scale for the separation of antioxidant compounds from different sources. They offer several advantages over conventional methods, in terms of high separation efficiency, low energy requirements, mild operating conditions, no additives, absence of phase transition, simple equipment, and easy scale-up. Pressure-driven membrane operations include microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO). These processes cover most of the “5-Stages Universal Recovery Processing” strategy since they can be used as macroscopic pretreatment (MF), in macro- and micro-molecule separation (UF), in purification (NF), and in concentration (RO).

These processes lead to the partial separation of the targeted compounds through size exclusion.

In addition to pressure-driven membrane operations, membrane distillation (MD), osmotic distillation (OD), and electrodialysis (ED) have emerged as new membrane technologies with great potential in integrated systems for the recovery of antioxidants from vegetable sources.

Antioxidants Recovery by Integrated Membrane Operations, Fig. 1 Schematic representation of antioxidants recovery by membrane operations (*MF*

microfiltration, *UF* ultrafiltration, *NF* nanofiltration, *RO* reverse osmosis, *OD* osmotic distillation, *MD* membrane distillation, *ED* electrodialysis)

In addition to RO, the concentration of bioactive compounds can be also performed by membrane distillation (MD) or osmotic distillation (OD). In these processes the driving force for the removal of water vapor across the pores of a hydrophobic membrane is given by a vapor pressure difference between the two sides of the membrane generated by a concentration (OD) or thermal (MD) gradient. Electrically driven processes, such as electrodialysis (ED) or a combination of ED with UF membranes (EDUF), have demonstrated very high selectivity for the separation of organic charged biomolecules. These processes use ion-exchange membranes and/or filtration membranes (such as UF) to separate molecules. The electric field is the main driving force involved in these processes. Molecular transfer is mainly due to the charge of the molecules and the flux depends on the strength of the electric field. In EDUF, fractionation of molecules is a function of their charges and molecular weights: according to the molecular weight cutoff of the UF membrane located in the cell,

low-molecular weight (MW) molecules cross the membrane, while higher-MW molecules remain in the feed.

Specific applications of pressure-driven and electrically driven membranes processes for the recovery of antioxidant molecules have been recently reviewed by Bazinet and Doyen (2016).

A schematic of integrated membrane operations, such as those previously described, for the recovery, separation, purification, and concentration of antioxidants, is depicted in Fig. 1. Such flow sheet is an example of flexible approach to valorize different agro-food by-products, as alternative to their disposal, within the logic of process intensification strategy.

A further improvement of the proposed integrated system has been recently investigated through the addition of a final step of membrane emulsification (EM) or biocatalytic membrane reactor (BMR) finalized to the formulation and valorization of antioxidant compounds in olive mill wastewaters (OMWWs) (Bazzarelli et al. 2015; Conidi et al. 2014).

► Scale Inhibitor

Antisolvent Membrane Crystallization

Gianluca Di Profio

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

This is an extension of the solvent evaporation membrane crystallization concept, where a porous membrane is used to dose the amount of antisolvent in the crystallizing solution, which has been proposed very recently (Di Profio et al. 2009). In this system, two operative configurations have been developed: solvent/antisolvent demixing and antisolvent addition membrane crystallization. In both cases, solvent/antisolvent migration occurs in vapor phase, according with the general concept of membrane crystallization and not by forcing it in liquid phase through the

membrane. The selective and precise dosing of the antisolvent, controlled by the porous membrane, allows a more fine control of the crystallizing solution composition during the process and at the nucleation point, with consequent advantages for the final crystal characteristics.

In solvent/antisolvent demixing configuration, a certain solute is dissolved in an appropriate mix of a solvent and an antisolvent whose composition is chosen in such a way that the solute remains indefinitely in the solution in the original conditions. When a gradient of chemical potential is generated between the two sides of the membranes, e.g., by a temperature difference, the solvent, which is supposed to have a higher vapor pressure than the antisolvent at the same temperature, evaporates at higher flow rate thus producing solvent/antisolvent demixing. As the amount of solvent in the mixture decreases, the lower solubility of the solute generates supersaturation and a phase separation occurs when the antisolvent exceeds a certain volume fraction. The requirements for this configuration are that: (i) the antisolvent and the solvent are miscible; (ii) the initial solvent/antisolvent balance in the mixture guarantees that the solute is under its solubility limit; and (iii) the solvent evaporates at higher velocity than the antisolvent. Crystallization of a solute from an aqueous/organic extraction mixture can be successfully carried out by this system.

In antisolvent addition configuration, a solute is dissolved in a solvent and then an antisolvent is gradually evaporated from the other side of the membrane by applying a gradient of chemical potential. As the antisolvent mixes with the solvent the solute dilutes but, at the same time, the composition of the mixture changes. At a certain point, the excess of antisolvent creates supersaturation and solute crystallization. This configuration requires that the antisolvent and the solvent are miscible. In this case, the compound to be crystallized can be soluble in aqueous solutions and poorly soluble in organic low boiling liquids.

Vapor Pressure–Temperature Relationship

History

Until the mid-nineteenth century, the prediction of the saturated vapor pressure of a liquid mixture or even of a pure liquid in relation with the temperature was not accurate despite the phenomena being studied long before the Middle ages. The Antoine equation, which solves this problem for pure components, is due to a French engineer (Louis Charles Antoine, 1825–1897) and was first published in “*Annales de Physique et de Chimie*” in 1891 (Antoine 1891). Antoine introduced an equation able to predict the vapor pressure of pure liquids (vaporization) and solids (sublimation). It is worth noting that this equation is still widely used today because of its accuracy. Wisniak (2001) has recently reviewed the historical development of the vapor pressure equations from Dalton to Antoine.

Phenomenon

The vapor pressure over a liquid is due to the thermodynamic equilibrium between the gas and

the liquid states of the component, which depends on the cohesive forces linking the molecules. In a closed cell, the vapor pressure of a pure component is a nonlinear relation of the temperature: the more the component is volatile, the more the vapor pressure is high.

Antoine Equation

For a given pure component in a closed cell, it calculates the saturated vapor pressure P (mmHg) with the temperature T (°C) as follows:

$$\log_{10} P = A - B/(T + C) \quad (1)$$

with A , B , and C being the Antoine coefficients, in mmHg and °C units, which are component-specific constants; e.g., for water : $A = 8.07131$; $B = 1730.63$ and $C = 233.426$ in the temperature range 1–99 °C.

Other forms of the Antoine equation can be deduced:

$$P = 10^{(A - B/(T + C))} \quad (2)$$

$$T = B/(A - \log_{10} P) - C \quad (3)$$

These equations fit very well for experimental vapor pressure data.

It is worth noting that the Antoine equation can also be used at high pressure or near the critical point. Indeed, for each component, two sets of parameters can be used according to the considered temperature range, i.e., either up to the normal boiling point or from normal boiling point to the critical point; in this last range, the Clausius-Clapeyron relation (Reid 1990) does not apply properly. In the case of pure water, in the temperature range 99–374 °C, the dedicated Antoine coefficients are $A = 8.140191$, $B = 1810.94$, and $C = 244.485$.

The extension (Wagner 1973) of the Antoine equation has been worked out to cover with a single set of parameters the whole temperature

Antoine Equation,

Fig. 1 Curves of $P_{\text{(sat) H}_2\text{O}}$ versus temperature; range 50–150 °C calculated with the Antoine equation

range going from the critical point to the triple point. This expression is required when computational techniques must be used.

On the other hand, a simplified equation using only two parameters was known to evaluate the vapor pressure; it was the August equation in which the parameter C is set to zero, thus assuming a temperature-independent heat of vaporization.

- For C coefficient, subtract 273.15 to take into account the modification of the temperature unit.

The Antoine coefficients have been tabulated for most of pure compounds. They can be obtained from various sources, including web access Data banks of Antoine Coefficients (visited June 2013).

Antoine Coefficients

Two systems of units can be used, either based on temperature and pressure, respectively, in °C and in mmHg or on K and Pa (SI system). Note that for historic reasons, the Antoine coefficients are still normally given based on the CGS system. Conversion from the historical system unit to the SI one can be made easily:

- B coefficient is the same in both systems;
- To get A coefficient in SI, add 2.124903 to the historical A; this value corresponds the pressure unit modification, i.e., to $\log_{10}(101325/760)$.

Example Calculation

This calculation has been done for water with the coefficients: $A = 8.07131$, $B = 1730.63$, and $C = 233.426$. The temperature validity range is from 1 °C to 100 °C.

- At $T = 50$ °C: $\log_{10}(P) = 8.07131 - 1730.63 / (50 + 233.426) = 1.9652$
- Hence, $P_{\text{(sat) H}_2\text{O}} = 92$ mmHg

The results shown in Fig. 1 and Table 1 correspond to water vapor pressure calculated with the respective sets of parameters of each domain with the Eq. 1. The discontinuity at 100 °C can be seen in the Table 1.

Antoine Equation, Table 1 Example calculation of $P_{(\text{sat})}$ H₂O; range 50–150 °C

T °C	log ₁₀ (P)	P mmHg	T °C	log ₁₀ (P)	P mmHg
50	1.9652012	92.30	100	2.8832575	764.29

Apple Juice and Membrane Operations

Carmela Conidi

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Apple juice is one of the most popular juices worldwide. It approximately accounts for a 20 % of the juice market share, with a production of 1.5 million tons per year. Besides vitamins and minerals, apple juice is characterized by high levels of

phenolic compounds. Most part of the juice is consumed as clarified product.

Traditional methods of processing apple juice are based on the use of several batch operations that are labor and time-consuming. Typically, after preliminary operations (sorting, washing, and peeling steps), apple fruits are crushed and then pressed.

The juice is submitted to a heat treatment for 16 s at temperature of 72 °C to inhibit yeast growth and avoid fermentation. During the pressing step, pectinase is added in order to hydrolyze the pectin, reducing juice viscosity and making the product easier to filter. This process is performed at temperatures in the range of 40 to 50 °C for 1 h. After this step, fining agents such as bentonite, gelatine, or silica solution are added to the juice to improve the effect of settling.

After decanting, the juice is submitted to a precoat filtration, using filter aids, i.e., diatomaceous earths and perlite, to remove suspended solids, colloidal particles, proteins, and polyphenols.

The final product can be submitted to a concentration process by evaporation. It is generally performed in multiple effect evaporators at temperatures between 45 °C and 90 °C. During this step, undesirable alterations of the original aroma profile of the juice due to high operating temperatures are produced.

Membrane operations are competitive and attractive alternatives to the conventional treatments of apple juices. The advantages of using membrane technology, over conventional methods, are related to product costs, working conditions, environmental aspects, and product quality.

Apple juice clarification, stabilization, recovery of aroma, and concentration are typical steps where membrane operations as microfiltration (MF), ultrafiltration (UF), enzymatic membrane reactors (EMR), pervaporation (PV), reverse osmosis (RO), osmotic distillation (OD), and membrane distillation (MD) are successfully utilized.

The clarification of apple juice by membrane processes has been used commercially for over 30 years. In particular, the use of MF and UF represents a valid alternative to traditional methods in apple juice clarification and stabilization, resulting in increase juice yield, improved product quality, and avoidance of fining agents (gelatin, bentonite, and silica sol) and filter aids that are costly and present disposal problems.

MF or UF permits the removal of haze-forming components, such as suspended solids, colloidal particles, and proteins resulting in the production of superior juice quality. Turbidity values less than 0.1–0.2 NTU are typically obtained if compared to 2–5 NTU of conventional methods with fining agents.

Polymeric membranes made from polyethersulfone (PES), polyvinylidene fluoride (PVDF), cellulose acetate (AC), and polysulfone (PS) with pore size of 0.1–0.2 μm and molecular weight cutoff (MWCO) of 10–100 kDa are used for the clarification of apple juice.

Tubular, capillary, and plate-and-frame membrane modules are the most important configurations used at industrial level.

The clarified juice is usually concentrated in order to reduce storage, package, and shipping costs. In addition, concentrated apple juice is more stable, presenting higher resistance to microbial and chemical deterioration than the original juice as a result of water activity reduction.

Conventional methods of apple juice concentration, such as vacuum evaporation, usually employ high temperature to remove water. However, heat determines undesirable changes of juice quality such as color changes, off-flavor formation, and reduction in the nutritional value.

RO is a pressure-driven membrane process that can be used as an alternative process for apple juice concentration, as it does not involve phase change or the use of high temperatures. The main advantages of RO concentration are the attainment of high-quality products due to low operating temperatures, resulting in the retention of nutritional compounds and lower energy consumption.

However, the performance of RO membranes is limited by the osmotic pressures of the juice when the concentration reaches values of 25–30 °Brix; therefore, RO can be considered an advantageous technique as a pre-concentration step.

Polyamide and cellulose acetate RO membranes in both tubular and spiral wound configurations have been extensively used during the concentration of apple juice (Alvarez et al. 2002).

In order to overcome the limitation of RO in apple juice concentration, more recently, osmotic distillation (OD) and membrane distillation (MD) have been proposed as attractive membrane processes for apple juice concentration allowing very high concentrations (up to 65 °Brix) to be reached under atmospheric pressure and at room temperature, thus avoiding thermal and mechanical damage (Onsekizoglu et al. 2010).

These different membrane-based concentration techniques resulted very efficient in the concentration of apple juice, since the concentrated juice presented nutritional and sensorial quality similar to that of the original juice, especially regarding the retention of the bright color and pleasant aroma, which are lost during thermal evaporation.

Esters, aldehydes, and alcohols such as ethyl butanoate, ethyl-2-methylbutanoate, and hexanal are the main compounds which contribute to the aroma profile of apple juice.

PV constitutes a promising alternative to traditional techniques, such as distillation and partial condensation, for aroma recovery from apple juices.

Alvarez et al. (2000) proposed an integrated membrane process for producing apple juice and apple juice aroma concentrates.

Apple Juice and Membrane Operations, Fig. 1 Membrane operations for the treatment of apple juice

The process involves the clarification of raw apple juice by using an enzymatic membrane reactor, an RO unit to pre-concentrate the clarified juice up to 25 °Brix, a PV unit to recover and concentrate aroma compounds, and a final evaporation step to concentrate the juice up to 72 °Brix.

Rejection of aroma compounds in the PV step exceeded 90 % for most compounds considered. Organoleptic evaluation of the clarified and concentrated juice resulted excellent in terms of odor and flavor. The final products were more clear and brilliant than apple juice produced by conventional methods.

An economic evaluation of the integrated membrane system indicated a reduction of the total capital investment of 14 % and an increase in process yield of 5 % when compared with the conventional process.

A conceptual process design based on the integration of membrane operations in apple juice processing is depicted in Fig. 1.

Application of FEEM to Monitoring Membrane Fouling

Raymond L. Legge

Department of Chemical Engineering, University of Waterloo, Waterloo, ON, Canada

FEEM refers to a fluorescence excitation-emission matrix that consists of a collection of intensity values for a group of excitation-emission pairs over a range of emission and excitation wavelengths. FEEM or fluorescence excitation-emission matrix is important in the context of monitoring membrane fouling because NOM, or natural organic matter, is a significant foulant in some cases for drinking water production, and some components of NOM are fluorescent. Fluorophores can be classified into two categories that can be described as intrinsic or extrinsic (Lakowicz 2006). Two of the three major fractions of NOM are intrinsic fluorophores: protein and humic substances. Other biological constituents that may end up in water may also be fluorescent and can contribute to the FEEM, but this will depend on the water source. For the protein component, the amino acids that can contribute to the fluorescent signal are tryptophan, tyrosine, and phenylalanine. The third component, the colloid/particulate matter, may be captured in the

Rayleigh scattering portion of the FEEM and is not necessarily fluorescent (Peiris et al. 2010a). This approach has the advantage that little or no sample preparation is required so analysis is rapid and can possibly be conducted online. Analysis of the FEEM data is required because it is rich in information, but various approaches are required to identify or correlate which components are contributing to fouling. Among the various approaches for analysis of the data is principle component analysis or PCA (Peiris et al. 2010b). The advantage of FEEM-based analysis is that this approach can provide potentially online information. Possible options that would allow data acquisition online would include flow through systems or fiber optic approaches. The data acquired can then be used in concert with instantaneous membrane flux or transmembrane pressure (TMP) measurements to garner more information related to the important foulants. Advantages of this approach are that water pretreatment strategies can be tuned or tailored to minimize the components that are contributing to the NOM-based fouling or to take appropriate action before membrane fouling becomes significant. Similarly, it may provide a useful technique for monitoring the membrane permeate for NOM constituents that may contribute to disinfection by-products (DBPs) which can serve as possible carcinogens.

Aptamer Membrane Functionalization

Thomas Schäfer

Institute for Polymer Materials (Polymat),
University of the Basque Country (UPV/EHU),
Donostia-San Sebastián, Spain

Aptamer Membrane Functionalization. Aptamers can be incorporated into adequate porous membrane structures in order to obtain stimulus-responsive membranes whose permeability is modulated via a molecular recognition event. The concept relies on the fact that aptamers can recognize very specifically a molecular target, upon which a significant conformational change can occur if the aptamer is designed accordingly. In this sense, aptamer-modified membranes follow the concept “structure determines separation.” The stimulus-responsive membranes so obtained therefore do not require a bulk stimulus, such as a change in temperature or pH, which makes them particularly interesting for being employed in biomedical separations or DNA-based nanodevices (Bhattacharyya et al. 2013). Incorporating the aptamer into an adequate porous structure, the aptamer conformational change upon target recognition can give rise to a hindered pore flow, modulating in this way the overall membrane permeability. Aptamer-target interactions can be highly specific, target concentration dependent, and do not involve the formation of chemical bonds but are physical. As a consequence, membranes functionalized with aptamers change their permeability depending on the target concentration and in a reversible manner. Figure 1 depicts the concept of a membrane pore

A

Aptamer Membrane Functionalization, Fig. 1 Scheme of a stimulus-responsive aptamer-functionalized membrane

Aptamer Membrane Functionalization, Fig. 2 Mesoporous particles (a), their size distribution (b), and the functionalization of mesoporous silica with an aptamer (c)

functionalized with a DNA-aptamer hairpin structure which changes its conformation upon a molecular stimulus such as adenosine 5'-monophosphate (AMP). In the absence of the target AMP, the aptamer-functionalized membrane pores remain

open and the membrane permeability maximum. Upon interaction with AMP, the aptamer undergoes a conformational change which significantly reduces the pore flow and, hence, overall membrane permeability.

Aptamer Membrane Functionalization, Fig. 3 Sequence of a DNA-aptamer hairpin that binds selectively to ATP (a), scheme of its conformational

change upon target recognition (b), and function to release in a reversible, specific, and concentration-dependent fashion cargo molecules (c)

For the conformational change to take effect, the pore diameter needs to be of the same order of magnitude. Therefore, mesoporous structures are preferably employed that furthermore possess a high degree of isoporosity. Aptamer-modulated pore flow has been thoroughly studied for mesoporous particles that are used as controlled delivery devices (Özalp and Schäfer 2011). Figure 2 shows the immobilization strategy for modifying mesoporous silica particles with aptamers and Fig. 3 the concept of how such an aptamer can serve as a reversibly opening “lid” in order to liberate cargo molecules upon target recognition (here: ATP).

A key parameter for the functioning of aptamer-functionalized membranes is the fine-tuning of the pore size within which the aptamer conformational change takes place. Pores too large would not result in any aptamer-modulated permeability, while pores too narrow would hinder the aptamer from freely changing its

conformation. It could be shown that the thickness change of a DNA-aptamer hairpin film amounts up to about 2 nm upon interaction with the target (Serrano-Santos et al. 2012). Hence, mesoporous structures with a pore diameter between 2 and 3 nm have been found to be a suitable base material for aptamer-functionalized particles and membranes (Özalp and Schäfer 2011).

Aptamer Screening

Thomas Schäfer

Institute for Polymer Materials (Polymat),
University of the Basque Country (UPV/EHU),
Donostia-San Sebastián, Spain

Aptamer screening or selection, also called systematic evolution of ligands by exponential enrichment (SELEX), is a combinatorial chemistry method by which aptamers (single-stranded DNA or RNA) are selected. SELEX is an evolutionary method driven by the binding of oligonucleotide sequences to a specific target based on their particular tridimensional structure, which confers high affinity and specificity. The selection process starts with a random oligonucleotide library consisting of a random region flanked by fixed primer regions required for PCR amplification. The random region confers outstanding variability, derived from the number of possible sequences in the library.

The variability of the library can be calculated with the expression 4^n , where 4 is the number of possibilities at each position (A, T, C, or G) and n is the length of the random region. SELEX allows the screening of oligonucleotide libraries

against a given target (i.e., protein, small molecules, or even whole cells) by an iterative process that involves (i) library/target interaction, (ii) selection of the sequences that bind to the target and removal of no binders, (iii) enrichment of the selected sequences by PCR, and (iv) after several screening rounds, cloning and sequencing to identify individual sequences. Finally, bioinformatic analysis is required to determine the most promising motifs or sequences. Next, the candidate sequences are evaluated to confirm their binding capability. SELEX technology could be compared to antibody production; however, SELEX offers interesting features that overcome some limitations of the antibody production, such as fast in vitro performance, no need for cells or animals, ease of selection under physiological or nonphysiological conditions, no limitation for target selection, and batch-to-batch reproducibility.

Since the first report of SELEX in 1992 by two independent groups (Tuerk and Gold 1990; Ellington and Szostak 1990), several modifications of the standard method have been reported to improve its performance. Nowadays, a significant number of aptamers have been selected and used as recognition molecules for environmental, food, diagnosis, and therapeutic applications (Fig. 1).

Aptamers

Thomas Schäfer
Institute for Polymer Materials (Polymat),
University of the Basque Country (UPV/EHU),
Donostia-San Sebastián, Spain

Aptamers (from Latin *aptus*, to fit) are artificial ligands binding with high affinity and specificity to their cognate target, selected through a Darwinian-like evolution method referred to as SELEX. Aptamers generally consist of structured single-strand nucleic acid molecules such as RNA and ssDNA; however, dsDNA and peptide aptamers have been described as well (Colas et al. 1996; Patel et al. 1997).

Aptamers can be selected against virtually any target and under nonphysiological conditions because no animal host is required. Hitherto, aptamers were selected against a broad range of target molecules, such as amino acids, peptides, proteins, drugs, organic and inorganic molecules, or even whole cells, with affinities often comparable to those of monoclonal antibodies.

The binding proprieties of aptamers are due to the formation of specific aptamer-target complexes stabilized by non-covalent interactions. The latter are a combination of van der Waals forces, hydrogen bonds, and electrostatic interactions. Binding of an aptamer to its cognate target can trigger an adaptive folding in which the target promotes and stabilizes the secondary and tertiary structures of aptamers. The dynamic conformations of free aptamers, consisting of labile knots, loops, and stems, turn into stable architectures within the aptamer-target complexes where noncanonical base pairing along with

intermolecular interactions creates unique binding pockets. Hence, along with a remarkable affinity, aptamers are generally characterized by high specificity. One of the most noteworthy examples is the anti-theophylline aptamer which can discriminate between theophylline and caffeine, two related molecules that only differ by a methyl group of the imidazole ring, having about 11,000 times higher affinity for the former. Similarly, aptamers have been reported to discriminate between enantiomers, macromolecules, proteins, and whole cells.

Apart from their high affinity and specificity, aptamers possess unique chemical and biochemical characteristics which clearly set them apart from other receptors. For example, aptamers are exceptionally stable: they may undergo denaturation, but the process is fully reversible within minutes; hence, temperature changes or long-term storage does not affect their functionality. Furthermore, the well-known chemistry of aptamers allows for site-directed chemical modifications and competitive production costs. New functional groups can be introduced a priori – within the SELEX process – using modified nucleic acid libraries or a posteriori modifying a selected DNA/RNA through chemical synthesis. While the first approach relies on the compatibility of the modification adopted with the enzymatic amplification necessary for selection, the latter approach is streamlined by detailed knowledge of the structure of both the aptamer and the aptamer-target complex. Since their first appearance in the early 1990s, aptamers have received constantly increasing attention, reflected in their use as diagnostic reagents and therapeutic compounds.

Aquaporin, a transmembrane protein, has attracted attention globally since its serendipitous discovery by Peter Agre in 1992 (Agre 2006). Its facilitation in rapid and selective water transport has inspired many scientists to utilize this unique function for water treatment applications (Kaufman et al. 2010; Wang et al. 2012). Much effort has been devoted to build and overcome the challenges faced in fabricating the synthetic biomimetic membrane housing the water channel (Kumar et al. 2012). It is envisioned that this technology will bring about higher efficiency for desalination (Kaufman and Freger 2011) and hence lower cost.

Membrane Preparation Methods

Aquaporin-incorporated membranes can be prepared via the (1) Langmuir-Blodgett (LB) and Langmuir-Schaefer (LS) monolayer transfer techniques, (2) vesicle rupture of

aquaporin-incorporated materials onto a porous support, or (3) autopainting membrane (APM) method.

LB and LS monolayer transfer (Sun et al. 2012): The first monolayer of amphiphilic materials (lipids or copolymers) is deposited onto a solid support by the LB method. The second monolayer, which contains aquaporin-incorporated amphiphilic materials, is subsequently deposited onto the first layer by the LS method.

Vesicle rupture: Aquaporins are first incorporated into liposomes (Borgnia et al. 1999; Wang et al. 2011) or polymersomes (Kumar et al. 2007) through a typical transmembrane protein incorporation method (Borgnia et al. 1999). Subsequently, these aquaporin-incorporated vesicles are ruptured onto a porous support via charge interaction (Wang et al. 2011; Kaufman et al. 2010; Li et al. 2012) or covalent conjugation between the vesicles and the support (Wang et al. 2012; Zhong et al. 2012; Duong et al. 2012).

APM method: Free-standing aquaporin-incorporated lipid/polymeric membranes can be formed analogous to the conventional black lipid membrane preparation method (Hansen et al. 2009; González-Pérez et al. 2009). A mixed solution of aquaporins and amphiphilic materials is smeared across the hydrophobic array's apertures in electrolyte conditions. The membranes are spontaneously formed on the apertures at the interface of organic and aqueous phases.

Aquaporin Biomimetic Membrane Designs

According to their conformations, the designs of aquaporin-embedded biomimetic membranes can be classified into two categories, namely, (1) free-standing lipidic/polymeric membranes (Fig. 1) and (2) supported lipidic/polymeric membranes (Fig. 2).

The free-standing lipidic/polymeric membrane is fabricated by assembling black lipid/block copolymer domains across multiple apertures in the ethylene tetrafluoroethylene (ETFE) scaffolds

(about 300 μm diameter each aperture) (Hansen et al. 2009; González-Pérez et al. 2009; Rein et al. 2011). This membrane array can be stabilized with the support of a highly permeable hydrogel layer (Lander et al. 2011; Ibragimova et al. 2012).

The supported lipidic/polymeric membranes with aquaporins have been designed for several applications, such as forward osmosis (FO), nanofiltration (NF), and reverse osmosis (RO). Detailed information on the materials and preliminary performance is summarized in Table 1.

Aquaporin-Incorporated Biomimetic Membranes, Fig. 1 Schematic graph of free-standing lipidic/polymeric membranes

Characterization of Water Transport Through the Aquaporin-Incorporated Membranes

The permeability of reconstituted aquaporin in vesicles is characterized mainly by the stopped-flow spectroscopy technique. In a stopped-flow experiment, the osmotic permeability P_f ($\text{m}^3/\text{m}^2/\text{s}$) can be calculated by using the equation (Borgnia et al. 1999)

$$P_f = k/C_{osm}V_w(S_o/V_o)$$

where k is the rate constant obtained from light scattering signal and $S_o(\text{m}^2)$ and $V_o(\text{m}^3)$ are the initial surface area and volume of the vesicle, respectively. V_w is the molar volume of water ($18 \times 10^{-6} \text{ m}^3/\text{mol}$) and C_{osm} is the osmolarity difference that drives the vesicle shrinkage.

The hydraulic permeability coefficient L_p (m/s/bar) represents the rate of water movement across a given area, per unit of osmotic gradient, and can be calculated from the equation (Hillyard 2012):

$$L_p = P_f V_w / RT$$

where R and T are gas constant and temperature, respectively. When the biomimetic membrane transforms from a sphere to a flat surface, the intrinsic water volume flux J_v (m^3/s) can be obtained by using equation (Hillyard 2012):

$$J_v = AL_p(\sigma\lambda RT\Delta C - \Delta P)$$

where A is the membrane area, in m^2 . σ is the reflection coefficient and is assumed to be 1. λ is

Aquaporins (AQPs) or Water Channels

Fabio Bazzarelli and Lidieta Giorno
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

Aquaporins (AQPs) or water channels are a family of integral membrane proteins that form hydrophilic pores in the cellular membrane. They are involved in the water transport through the membrane.

All cells depend on their ability to maintain water homeostasis. This is achieved through the action of aquaporins, membrane-bound water channels that facilitate water flow across cellular membrane along osmotic gradients, while excluding the passage of ions and protons. It is required for maintenance of the membrane potential and

intracellular pH. As with any membrane transport facilitator, aquaporins have evolved to be highly selective for their transported substrate without binding water so strongly that transport is inhibited. On the basis of their selectivity, aquaporins can be divided into two groups: the ordinary aquaporins, permeable to water only, and aquaglyceroporins which also permit transport of small solutes such as glycerol and urea. A number of other compounds have also been reported to be transported through aquaporins, including CO₂, NH₃, and arsenite (Kreida and Tornroth-Horsefield 2015). AQPs are transmembrane channels; thus the ability of a molecule to cross an AQP channel depends on its own characteristics (size, polarity, charge) and on the features of the AQP involved (Di Giorgio et al. 2014). They have a similar basic structure; AQPs are monomers of about 30 kDa and, in general, contain six membrane-spanning helical segments and two shorter helical segments that do not span the entire membrane. The AQPs generally form stable tetramers in membranes, although each monomer contains a separate water pore. High-resolution structural data show that the membrane-spanning helical domains surround cytoplasmic and extracellular vestibules that are connected by a narrow aqueous pore. Structural data and molecular dynamics simulations suggest that water molecules move through this narrow aqueous pore and that steric and electrostatic factors are responsible for the water selectivity of AQPs. The pore is less constricted in the aquaglyceroporins than in the water-selective AQPs (diameter of 3.4 Å versus 2.8 Å, respectively) and is lined by more hydrophobic residues (Papadopoulos and Verkman 2013). An important property of aquaporin-mediated water transport is its ability to be regulated in response to cellular or environmental signals. This is achieved by controlling water transport at the individual protein level through a conformational change, so-called gating, or by altering the aquaporin density of a particular membrane. These proteins are present in all kingdoms of life, demonstrating their central role in maintaining normal physiology of all organisms. The first member of this family, AQP1, was identified in erythrocytes in 1991.

This discovery led to homology cloning of hundreds of AQPs homologues from throughout the animal and plant kingdoms, as well as from lower organisms.

In humans there have been identified 13 aquaporins (AQP0–12) with specific organ, tissue, and cellular localization. Thus, different members of the AQPs family are expected to function in virtually all physiological processes that involve water transport across the membrane.

The AQPs are expressed in many cell types involved in fluid transport, including epithelia and endothelia in the kidney, lung, exocrine glands, eyes, and gastrointestinal tract. However, aquaporins are also expressed in cells that do not have an obvious role in fluid transport, such as erythrocytes and some leukocytes, adipocytes, and muscle. In addition, these are also expressed in astrocytes throughout the central nervous system and in supportive cells. Aquaporins have been linked to a number of pathological conditions, including brain edema, renal disease, obesity, and cancer, raising their attractiveness as drug targets.

Given the key role played by aquaporins in the kidney, for recovering water permeated together with other ions and molecules through the first part of the glomerulus, they have been investigated for developing biohybrid membranes able to desalinate seawater. The biohybrid membranes containing aquaporins showed very high water selectivity and permeability. Technological challenges for productive application include biohybrid membrane preparation on a large scale, aquaporin stability under operating conditions or during membrane module cleaning, and maintenance operation. Development of synthetic water channels mimicking aquaporins is a new strategy under investigation. Highly selective and permeable water channels are very interesting for the development of seawater desalination plant operating with very low energy input.

Aromatic and Nonaromatic Separation by Membrane Operations

Lan Ying Jiang

School of Metallurgy and Environment, Central South University, Changsha, China

Synonyms

[Dearomatization by membrane operations](#)

Efficient separation of aromatics/nonaromatics (generally referred to as dearomatization) is of great interest and significance to the chemical and petrochemical industries (Kung et al. 2010). Aromatic hydrocarbons such as toluene, benzene, ethylbenzene, and xylenes are important feedstock in petrochemical industry; therefore, purification of aromatics is desired after they are produced through catalytic reforming, cracking, or other processes (Sittig 1976). Nonaromatics also have a wide range of applications (e.g., solvents, fuels). They are generally derived from aromatics/nonaromatics mixed feed, which necessitates the separation of aromatic and nonaromatic hydrocarbons. For example, removal of aromatic hydrocarbons is needed to enhance the thermal and oxidation stability, viscosity, and color of lube oils. Aromatics such as benzene is carcinogenic; it is regulated by law that the levels of aromatics in petrol and solvents must be controlled (Singh et al. 2003). Removal of aromatics by-products will facilitate the improvement in the production efficiency of some petrochemical processes, such as ethylene production through steam cracking (Corma et al. 2005).

Presently, great interest from academia and industry is given to studying the separation of aromatic/nonaromatic by membrane process, which is pervaporation specifically due to the dense structure of its membrane capable of discriminating molecular-level difference as encountered in hydrocarbon mixtures. The separation in this process is based on the differential sorption and diffusion of permeating components inside membrane matrix, coupled with the intrinsic volatility difference of permeating components. It is the involvement of selective membrane that makes pervaporation process independent of the vapor–liquid equilibrium and therefore more energy efficient and environment friendly than classical distillation, rectification, extraction, and crystallization.

Numerous polymeric materials and some inorganic materials as well as their derivatives by chemical (e.g., grafting, cross-linking) or physical modifications (e.g., polymer blending, inorganic filling) have been applied in preparing pervaporation membrane for aromatics/nonaromatic separation (Smith et al. 2004). Aromatics have double-bond-related π -electrons, hence having affinity toward membrane matrix containing polar functional groups. Size selection also favors the aromatics in the separation of some aromatic/nonaromatic pairs. A typical pair is benzene/cyclohexane wherein the former has smaller molar volume. All of the organic and inorganic materials utilized show preferential transport toward aromatics. Carbon-modified nylon 6 exhibited an extremely high separation factor of more than 400. Commercialized polyvinyl alcohol composite membrane also presents recommendable separation factor and flux. As an effort toward practical application, integrally skinned asymmetric polymeric membranes for toluene/iso-octane separation were fabricated from blends of commercially available polybenzimidazole (PBI) and polyimide (PI) Matrimid using dry-jet wet spinning followed by non-solvent-induced phase inversion (Kung et al. 2010). The best performance achieved is a separation factor of 200 and a flux of 1.35 kg/m²-h in separating toluene/iso-octane (50/50 wt%). Separation factor for the selective transport of toluene increases with higher polybenzimidazole

content, while total flux is correspondingly reduced. This is because PBI has stronger polarity, tighter and more rigid structure, as well as enhanced anti-swelling property.

A pervaporation process alone might not be an economical choice for aromatic/nonaromatic separation. In the comparison among a conventional extractive distillation process alone, a pervaporation system alone, and a hybrid system consisting of the two processes in benzene/cyclohexane separation, it is found that a hybrid system is more economical than either of the two single processes (Rautenbach and Albrecht 1985). The feed solution used for the evaluation is 1:1 (mol/mol) benzene/cyclohexane, and the target is to separate this mixture into two streams: 99.5 mol% benzene and 99.2 mol% cyclohexane. In both extractive distillation process and hybrid process, furfural was used to break the benzene/cyclohexane azeotrope in the first stage. The product from this stage is a cyclohexane-rich stream and a mixture of benzene/furfural. The benzene impurity in the cyclohexane-enriched stream is then removed by pervaporation, and the benzene/furfural mixture is separated by distillation to get furfural and highly purified benzene. The advantage of hybrid system is more striking when higher purity is demanded of the products.

Artificial Biological Membrane

► Bioartificial Synthetic Membrane

Artificial Blood Cell

Antonietta Messina and Loredana De Bartolo
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

The expression *artificial blood* refers to artificial substitutes or artificial surrogates purposely designed in laboratory in order to mimic and fulfill two specific functions of the biological blood: the transport of oxygen and carbon dioxide throughout the body and the maintenance of the hemostasis inducing the blood clotting. Actually, the blood is a special type of connective tissue composed of four different components in charge of a variety of functions. The white cells, responsible for the immune defense; the red cells, responsible for the transportation of oxygen and carbon dioxide throughout the body; the platelets, involved in the hemostasis process; and the plasma, an extracellular component made up of water, salts, and various proteins that, along with platelets, encourages blood to clot. Actually, due to this complex composition, it is not possible to reproduce the blood artificially and only two of its components are laboratory designed: **the red blood cells and the platelet substitutes**. The artificial blood products have advantageous characteristics nowadays:

- They are safe and biocompatible and lacking of the membrane antigens; therefore they are usable for all patient blood types.
- They are able to transport oxygen throughout the body and release it where needed.
- They possess a great level of safety. They can be processed by filtration and pasteurization to remove all disease-causing agents such as viruses and microorganisms.

- They have a long shelf life. Unlike donated blood that breaks down after 1 month, artificial blood can be stored for over a year or more and it can be stocked and easily shipped where needed (Suman 2008; Cohn 2000; Nucci and Abuchowski 1998; Lesley 2001).

A brief history. Though popular folklore suggests that Maya Empire was trying to find a blood substitute, it is only after William Harvey discovered and described the blood pathways and circulation throughout the body, in 1616, that medical practitioners tried numerous substances such as milk, beer, plant resins, urine, and animal blood as a substitute for blood. Therefore, the first successful human blood transfusion was done in 1667. Only in 1868, researchers found that solutions containing hemoglobin isolated from red blood cells could be used as blood replacements. Therefore, the most important turning point in the development of artificial blood was made in 1883 and 1890s with the development of the Ringer's solution and the discovery by Karl Landsteiner of the human blood groups (A, B, AB, and O) according to the capacity of their red cells to express on their membrane surface specific antigens (Suman 2008; Nucci and Abuchowski 1998).

As already said, there are two different products under development as blood substitutes. They differ primarily in their functions: they carry oxygen or induce the blood clotting.

Red blood cell substitutes. They are classified in hemoglobin-based and perfluorocarbon (PFC)-based substitutes. **Hemoglobin-based products.** Derived from different sources (animal, human, recombinant) all hemoglobin products carry oxygen by taking advantage of the natural hemoglobin function. The natural hemoglobin products are obtained from human or animal blood. The human substitutes, in particular, are derived from blood and red cells collected during plasma donations. The synthetic products, on the contrary, are the results of amino acids specific combinations or the outcome of the recombinant biochemical technology, which allow to derive hemoglobin harvested from an *E. coli* bacteria strain. Independently on the sources, the protein breaks down easily into

smaller, toxic compounds. Then once obtained, it must undergo purification and partial modification in order to decrease (i) the rapid formation of dimers and monomers that freely diffuse into renal tubules causing renal failure and (ii) its strong affinity for factors (i.e., NO) causing vasoconstriction, hypertension, and bradycardia. Among the strategies employed to stabilize hemoglobin the main important are the chemically cross-linking molecule processes and the encapsulation technology. Polyethylene Glycol-Modified, Liposome-Encapsulated Hemoglobin, and Polymersome-encapsulated hemoglobin have been produced and commercialized (Enzon and APEX Bioscience) for the treatment of cancer and stroke patients and for treatment of hypotension induced by septic shock respectively (Chang 1998). Moreover, hemoglobin products covalently cross-linked with small bridges of sugar molecules showed not to induce vasoconstriction in phase III of clinical trials (Gould and Moss 1996; Danielson et al. 1997).

Perfluorocarbon (PFC) products. PFC-based solutions are synthetic hydrocarbons with halide substitutions able to dissolve up to 50 times more oxygen than plasma. These biologically inert materials allow to avoid the spreading of infectious disease via a blood transfusion. Nevertheless, they are not soluble in water solution and require to be emulsified in oils or lipids before being injected into patients' blood. Despite that a special product, developed by the PFC therapeutics, is currently in phase III of clinical trials for use in cardiac and general surgical patients, currently these substitutes showed to have a short duration of action, about 24 h, to be very expensive, and to cause some adverse reactions associated with their long-term usage. Their prolonged administration can cause several adverse reactions such as the increase of the blood pressure and of the pancreatic proteins, the gastrointestinal dysmobility, thrombocytopenia, flu-like syndrome, and a quite important oxygen toxicity (Suman 2008; Cohn 2000; Lesley 2001).

Platelet substitutes. These artificial products are very different from those already described. Classified in Platelet-Derived Products and

Platelet substitutes, they represent an essential component of the thrombogenic response to bleeding through the adhesion to the damaged vessel lining and releasing several coagulation factors. **Platelet-Derived Products.** Frozen platelets and cold liquid-stored platelets have been tested since 1950s in order to develop a treatment for thrombocytopenia. Despite being the only alternative to fresh platelets in clinical use, disadvantages as expensiveness with respect to the fresh platelets, morphological defects, and lower functionality directed the research toward new discoveries. The **Lyophilized platelet products** were developed since 1950s and are currently under animal trials. They are obtained by fixing human platelets in paraformaldehyde prior to freeze-drying them in an albumin solution with no influences on the adhesive properties of the cells. The **Platelet microparticles** are microvesicles formed spontaneously during the storage. Deriving from the platelet membranes, they showed similar hemostatic properties as intact platelets. Cypriss Bioscience developed **Infusive Platelet Membranes** (IPM; Cyplex, Cypriss Bioscience) using outdated human platelet that are purposely fragmented, virally inactivated, and lyophilized (Lesley 2001). With a shelf life of over 2 years these products are in phase II of clinical trials and appeared to be able to stop the bleeding in the 60 % of the patients resulted refractory to platelet transfusion due to the immune response to HLA or platelet antigens, with no adverse effects or risks of thrombosis. In order to overcome the disadvantages of the platelet processing, storage, and shelf life **Platelet Substitutes** have been proposed. The **Red cells with surface-bound fibrinogen or RGD peptides** have been subjected to numerous studies. Fibrinogen is a free molecule able to bind activated platelets together through the multiple Arginine-Glycine-Aspartate (RGD) sequences. Bounding to the surface of autologous erythrocytes (red blood cells), fibrinogen, or the RGD fragments, the "thromboerythrocytes" obtained showed to be hemostatically effective in some animal models of thrombocytopenia. Other important products are the **Fibrinogen-coated albumin**

microcapsules/microspheres. These are coated with fibrinogen of the human protein albumin. Two preparations have been evaluated in preclinical trials: SynthocytesTM (Andaris Group Ltd, Nottingham, UK) and ThrombospheresTM (Hemisphere, Irvine, Calif). The latter, due to their smaller mean diameter, showed in vivo to have a long duration of action. Last, two **Liposome-based agents** have been studied: the *plateletsomes*, which are lipid vesicles with platelet glycoproteins on their surface, and the *factor Xa* with phospholipid vesicles. Both demonstrated to be hemostatically effective in vitro and in some animal models, but problems of high toxicity must be overcome in order to pass the clinical trials.

Despite that numerous new discoveries and products showed to be useful as blood substitutes, the current artificial blood technology is limited by the short-term shelf life, the costs, and the toxicity problems clinically proved. Then new materials able to carry oxygen in the body and to induce the blood clot must be found and longer-lasting products should be developed (Suman 2008; Lesley 2001; Lee and Blajchman 1998).

Artificial Brain Model: Biohybrid Membrane System

Sabrina Morelli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Artificial brain, in membrane operation, is a biohybrid membrane system which provides suitable conditions for the creation of a biomimetic microenvironment for neuronal tissue engineering resembling in vivo neuronal tissue properties and functions.

In the last decade, neuronal cell behavior on biomaterial such as membrane has become of great interest since it offers the advantage of developing neuronal tissue that may be used for the in vitro simulation of human brain function substitute. This could provide further insights not only into the cell but also in developing therapies in neurodegenerative disorders such as Parkinson's or Alzheimer's diseases. A biohybrid system using neurons could also represent a useful instrument for predictive drug testing or constitute a future model of a bioneuronal network device. To accomplish this task the artificial membrane must exhibit a specific micro-architecture able to stimulate neuronal regeneration, therefore supporting axonal regrowth and affecting cellular orientation and differentiation in a positive way.

This biohybrid artificial system consisting of neurons and membranes offers a valuable tool for studying neuronal cell behavior and fundamental questions in neuroscientific research, and it also could be used in a wide range of biotechnological applications.

Several works in the literature show evidence that semipermeable polymeric membranes in flat and hollow fiber configurations, thanks to their highly selective structural, physicochemical, and transport properties, allow the successful in vitro reconstruction of neuronal tissue reproducing a tissue model for studying metabolic diseases and

drug effects (De Bartolo et al. 2008; Zhang et al. 2005; Morelli et al. 2014; Piscioneri et al. 2015).

For typical neuronal tissue-engineered constructs, the properties of the material components relevant to the tissue response include the surface microgeometry, the MWCO, the electrical properties, possibly the bioactive factors that are loaded and sustainably released through the channel wall, and the degradation rate for biodegradable materials. The wettability of the membrane surface has proved to be a factor that affects the growth of neurons modulating the adsorption of adhesion proteins contained in the culture medium or secreted by cells that mediate the adhesion of cells to the substrate.

Advances in polymer chemistry have facilitated the engineering of synthetic membranes that can be specifically manipulated with regard to their physical and mechanical characteristics, which may affect the interactions with cells.

The influence of topographical features on neuronal cell adhesion and differentiation has been studied by using patterned adhesive areas that provide only a fraction of the surface for cell adhesion while the rest is cell repellent or by using contact guidance cues in combination with also nerve growth factors or an electric field. Topographic guidance of neurite outgrowth has been explored in vitro with a culture substrate containing etches, microchannels, nanotubes, or microgrooves. Micro-patterned biodegradable poly(L-lactic acid) membranes directly improved the guidance of neurite extension and thereby enhanced their orientation with a consequently highly ordered neuronal cell matrix, which may have strong bearings on the elucidation of regeneration mechanisms (Morelli et al. 2010).

Hippocampal neurons exhibited a different morphology in response to varying the properties of the membrane surface. Indeed, cells grown on the smoother membranes such as fluorocarbon (FC) and PES membranes displayed a large number of neuritis with consequent formation of bundles. The density of axonal network increases the neurites to become more elaborate and highly branched on the smoother surfaces.

The importance of FC membrane culture substrates toward the highlighting of the effects of highly preferred GABA_AR α 2,5 agonists and inverse agonists on the successful elongation of neuronal processes and transcriptional activities of hamster hippocampal Gluergic cells was demonstrated for the first time (Giusi et al. 2009).

A biohybrid system composed of neuronal cells and silicon-supported nanoporous membranes has been designed to facilitate control of the biochemical environment of neuronal networks with cellular resolution. Nanoporous membranes may be used to interface with biological materials in a biohybrid system, for example, as an artificial chemical synapse interface (Wolftrum et al. 2006).

Compared to traditional two-dimensional (2D) culture systems, 3D in vitro cultures of neuronal cells appear to better mimic in vivo neuronal microenvironments representing a great potential for building 3D neuronal circuits as well as for creating tissue-based biosensors and for promoting systemic restoration of severe nerve injuries. In this context, several studies have been performed toward the determination of differences between 2D and 3D environments for neuronal function in order to provide great benefit to neuroengineering efforts. Recently, a complete 3D neural tissue-like structure has been assembled in vitro using primary hippocampal cells and PAN HF membranes. As a consequence, this advanced model system could allow the mimicking of hippocampal neuronal events in order to study natural neurobiological properties of these cells, such as memory and learning processes, or the induction of disease pathologies, allowing testing of new therapies on the resolution of these states (Morelli et al. 2012).

In the last decade, with rapid advances in biomaterial technology, several types of natural and synthetic biodegradable polymer, including collagen, chitosan, poly(glycolic acid), poly(L-lactic acid), poly(L-lactide-co-glycolide), poly(caprolactone), and polyurethane, have been reported as suitable for nerve regeneration, although the ideal physicochemical compositions, surface structure, and functionalization of such

materials have not yet been found. It was recently reported that polycaprolactone-based membranes successfully supported outgrowth and differentiation of human neuronal cells (Morelli et al. 2015).

Artificial Kidney

Sabrina Morelli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Artificial kidney, a synonym for hemodialyzer, is an extracorporeal device through which blood may be circulated for removal of elements that normally are excreted in the urine.

The artificial kidney is used to rid the blood of metabolic products, to correct electrolyte-water and acid-alkaline balances in acute and chronic renal insufficiency, to remove dialyzing toxic substances in cases of poisoning, and to remove excess water in cases of edema. In 1913 the American scientist Abel created an apparatus for dialysis that was the basis for the artificial kidney; Dr. Willem Kolff, a Dutch physician, constructed the first functioning artificial kidney. He treated his first patient in 1943, and in 1945 he was first able to save a patient's life with hemodialysis treatment.

The artificial kidney operates on the principle of the dialysis of substances through a semipermeable membrane. Dialysis is a result of the differences in the concentrations of substances in the blood and in the dialyzing solution, which contains glucose and the principal electrolytes of the blood in nearly physiological concentrations without containing any of the substances that must be removed from the body (urea, creatinine, uric acid, sulfates, phosphates). Proteins, formed elements of the blood, bacteria, and substances with a molecular weight of more than 30,000, do not pass through the membrane. During hemodialysis the patient's blood is drawn off through a catheter by a pump from the inferior vena cava and passed inside the chambers of membranes of the dialyzer; these chambers are washed outside by the dialyzing solution, which is supplied by another pump. Partially purified, the blood is returned to one of the surface veins.

Artificial Functional Organ

► Membrane Artificial Organs

The membrane used during hemodialysis has evolved significantly since the earliest reports. Early membranes were natural materials, such as cellulose, or simple synthetic compositions, such as polysulfone, with symmetric structures and good performance for small solute passage (Fleming 2011).

However, these membranes include significant interactions with the complement pathway and immune response. Modifying the hydroxyl groups on cellulose membranes gives similar performance characteristics and less bioactivity and includes cellulose diacetate and hemophan membranes. With improvements in chemical engineering and manufacturing, cellulose-based membranes have yielded to synthetic membranes. The most popular membranes in use today are polyacrylonitrile and polysulfone; however, polyamide, polycarbonate, and polymethylmethacrylate are available. These materials have improved biocompatibility and reduce complement activation; however, they may enhance protein adsorption to the membrane in the absence of further modification. Despite the improved compatibility of synthetic membranes, the most recent large review does not demonstrate benefits conveyed by biocompatibility. The ultrastructure of membranes is predominantly the capillary design, or hollow fiber structure, in which blood flows through a series of small tubes held together in a bundle. This allows for a low-resistance, high surface area membrane. Membrane properties such as charge, wall thickness, and pore size affect function. The radius of the pore is related to the ultrafiltrate flow through the membrane, but overall fluid transfer is a function of the mean pore size. The number or density of pores and the radius of the pore affect solute transfer in diffusive clearances. Membrane characteristics such as flux and permeability to water are determinants of pore characteristics and wall thickness (Vigano et al. 2008).

As dialysis membrane technology has improved, high-flux membranes with larger pore sizes have been developed to allow greater clearances of larger retention molecules with

reduced induction of inflammatory mediators. While observational studies suggest that high-flux hemodialysis is associated with lower and dialysis-related amyloidosis, individual randomized controlled trials have not confirmed that high-flux hemodialysis improves clinical outcomes. High-flux dialysis membranes have larger pore sizes that may increase transportation of dialysate impurities or contaminants from the dialysate to the bloodstream even when the dialysate quality complies with acceptable standards, although some evidence suggests that high-flux membranes may actively absorb endotoxins and impede their back transfer from dialysate into the bloodstream (Palmer and Strippoli 2013).

Although dialysis is currently an available treatment for chronic renal disease, it replaces only the filtration function of the kidneys, and thus, it is associated with a number of complications and is not a permanent solution. Kidney transplantation performed in a heterotopic location is the only definitive solution for end-stage renal failure. A potential solution to ease the demand for donor kidneys may be the use of tissue engineering techniques that could be used to develop functional kidneys. A primary challenge in renal tissue engineering, however, is the production of tissues with the functional complexity required for kidney transplantation. The first step in achieving this aim could be to produce acellular kidney matrices for use as biological scaffolds that support cell growth and facilitate new tissue formation by potentiating cell–cell interaction. Several groups have used different perfusion-based decellularization protocols to produce naturally derived kidney scaffolds (Arenas-Herrera et al. 2013).

In the last decade, several studies have been performed on the development of the implantable artificial kidneys, but these studies reported only developmental concepts, in vitro or in vivo studies using small animals. It is difficult to control certain research aspects of an implantable artificial kidney to a preclinical level, and these aspects include long-term maintenance of the

antithrombogenic properties of the systems and each of its components, and the function of an implanted, miniaturized system, whose function must be maintained for a year's duration. Further progress in nanotechnology and biotechnology is required to realize a treatment with an implantable kidney (Saito et al. 2011).

New directions in dialysis research include cheaper treatments, home-based therapies, and simpler methods of blood purification. These objectives may be probably obtained with innovations in the field of artificial kidney through the utilization of new disciplines such as miniaturization, microfluidics, and nanotechnology. This research may lead to a new era of dialysis in which the new challenges are transportability, wearability, and why not the possibility to develop implantable devices (Ronco et al. 2011).

Artificial Liver, Membrane Operations

Antonietta Messina and Loredana De Bartolo
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

The expression of artificial liver defines all the supporting membrane systems able to substitute or integrate the liver functions when it reaches the 30 % critical threshold of the normal hepatic activity. The liver is the biggest glandular organs in the human body. Placed in the upper section of the abdominal cavity, this dark red organ is well known to be able to self-regenerate from partial injuries doubling its mass in 1 day. Therefore, acute or chronic hepatic insufficiencies caused by viral pathology, drug abuse, intoxications, or pathological decompensation can result in severe liver failure (LF). Though implying the inability of the liver to completely carry out its metabolic, excretory, and detoxifying functions, both the acute and chronic hepatic insufficiency (ALF, ACLF) can potentially be reversible if one third of the organ is still functioning; then liver activity can return to good levels. However, the LF leads to an accumulation of water-soluble and albumin-bounded toxins that cause encephalopathy and a multi-organ dysfunction. The solely long-term therapy to stem a hepatic insufficiency is the orthotopic transplantation that ensures a notable recovery of hepatocytes in number and functionality. Actually, due to the limited number of donors, only a narrow circle of patients in waiting list can be transplanted according to the severity of their disease. Thus, in order to improve patients' prognosis and survival, artificial extra-corporeal liver assist devices have been developed either "bridging" the patient to transplantation and temporarily supporting the failing organ until it is able to regenerate. Basically, three different types of supportive therapies are nowadays available: bio-artificial, artificial, and hybrid liver support

Artificial Liver

► Bioartificial Liver

systems. Therefore, between them, the artificial systems are the most used in clinic due to the lower costs and their easier handling. Artificial liver support systems are cell-free membrane devices aimed to temporally replace native liver detoxification functions through processes of adsorption and filtration in order to improve the clinical state of the patient. The most of artificial liver devices use membrane separation associated with columns or suspensions of sorbents (e.g., charcoal, anion-exchange or cation-exchange resins) that selectively remove toxins and/or regenerate dialysate or plasma filtrate (Carpentier et al. 2009; Naruse et al. 2007). Conventional dialysis techniques, such as hemofiltration, hemodialysis, or hemodiafiltration, have been used for the removal of the low molecular weight water-soluble metabolites. The *hemodialysis* allows to remove water-soluble metabolites, to re-equilibrate the acid-basic and the electrolytic values in the blood, and to reduce also the ammonia concentrations. The *hemofiltration* is carried out by filtrating cellulose or polysulfone membranes with a MWCO of 50 KDa. These membrane devices remove toxic and natural substances through connective transport allowing to partially recover from the hepatic encephalopathy. The *hemoperfusion* is performed through extracorporeal devices constituted by active charcoal adsorbing elements covered by a cellulose or polysulfone hemocompatible film. Adsorbing a variety of water-soluble toxins in the low and middle molecular weight range, the hemoperfusion has a significant disadvantage; in fact it has been demonstrated that the resulting patient's plasma can be highly impoverished of important biological substances causing important decompensation in patients' metabolism. In order to improve the specificity of the detoxification process, *membrane reactors containing immobilized enzymes* have been developed. Hepatic enzymes are definitively linked onto hollow fiber membranes or enclosed in microcapsules and showed to be able to enhance the recovery of the patients' mental state; hence, the percentage of surviving patients does not increase, and the clinical application is very limited. The *plasma exchange/plasmapheresis* is another

artificial support system for treating the LF. The cellular components of the blood are separated from the plasma using a hollow fiber filter (cellulose diacetate or polyethylene) able to remove toxins and supply lacking components as albumin or coagulation factors. However, this method has a disadvantage: it requires a large plasma stock with ensuing higher costs and bears the risk of infections. Moreover, most of the toxins that accumulate in the plasma of patients with liver insufficiency are protein bound; then these methods are not able to adequately eliminate them. This is the reason why new dialysis systems have been developed using albumin as scavenger to clear the toxins involved in the physiopathology of the failing liver. Between the different albumin dialysis modalities, the single-pass albumin dialysis (SPAD) has shown some positive results. The patient's blood passes a high-flux dialysis membrane, while an albumin solution streams counter-directionally to the filtering blood membrane, accepting toxins from the plasma. Therefore, the system works at a very high cost due to the high concentration of albumin needed in the dialysate to perform the plasma detoxification (Naruse et al. 2007; Onodera et al. 2006). At present, there are only two artificial extracorporeal liver support systems used in clinic: the *Molecular Adsorbents Recirculating System* (MARS[®]) from Gambro and *Fractionated Plasma Separation and Adsorption* (FPSA), which was designed by Fresenius Medical Care (Bad Homburg, Germany) and commercialized as Prometheus[®] (Carpentier et al. 2009; Evenepoel et al. 2006).

MARS is the most used artificial liver support system. Introduced in clinics in 1993, it consists of three components: (A) a conventional dialysis machine that guides the extracorporeal blood circuit (MARSFLUX), (B) a supplementary device for the albumin circuit made of two different adsorption columns (MARS AC250, MARS IE250), and (C) a dialysate circuit for low flux dialysis (Rademacher et al. 2011). *How it works*: the patient's blood is pumped in the blood circuit throughout a double-lumen central venous catheter. Here a first column, the MARSFLUX system, contains a polysulfone membrane with MWCO of

50 KDa that filters the blood and allows the passage through the membrane of the water-soluble molecules and the free toxins, retaining the albumin due to its higher dimension. In the meantime, the second circuit pushes in counter direction with respect to blood flux, a 20 % albumin solution that induces the dissociation of the protein-bounded toxins freeing the albumin of the plasma. The dialysate albumin, now saturated, is then restored passing through two adsorption columns in the second circuit: the MARS AC250 filled with active charcoal that retains high molecular weight molecules (bilirubin) and the MARS IE250 filled with the anion-exchange resin cholestyramine that retains the negative-charged molecules. Albumin solution of the second circuit is then restored and can be used for a new cycle of treatment. The MARS is recommended for treating both acute and chronic liver failure, despite the survival of patients is only partially increased. Therefore, many positive clinical results have been recorded for the patients in the last years such as the increase of the arterial pressure values and the systemic vascular resistance index, the attenuation of hyperdynamic circulation, and the significant decrease not only for bilirubin but also for creatinine and urea (Evenepoel et al. 2006; Rozga 2006).

The Prometheus artificial system realizes the combined removal of the albumin-bounded and the water-soluble toxins by means of adsorption and fractionated plasma separation. It was developed by Falkenhagen in 1999, and the system is based on FPSA combined with hemodialysis and consists of two circuits (Falkenhagen et al. 1999). In the first one, the blood is collected through the double-lumen catheter and allowed to flow through a polysulfone membrane. Its MWCO of 250 KDa allows either the free toxins or the plasma albumin-bounded toxins to pass through the membrane reaching the second circuit. Here the plasma is purified by a direct adsorption process into the same two columns of MARS: the anion-exchange column and the neutral resin column. Then the blood is recombined with the non-treated fraction and dialyzed completely in a high-flux device for the water-soluble molecules' removal (Evenepoel et al. 2006; Rozga 2006).

In the last decades, other dialysis albumin circuits have been developed for LF treatment, such as the *continuous veno-venous hemodialysis* (CVVHD) and the *continuous veno-venous hemodiafiltration* (CVVHDF); therefore, though being able to decrease the load of water-soluble toxins, they cannot provide the complete plasma treatment. The last available artificial liver is named *selective plasma filtration therapy* system (SEPET). In this system, the patient's blood passes through a single-use cartridge constituted by hollow fibers with MWCO of 100 kDa allowing molecules with a molecular weight close to 100 kDa to pass the membrane in only limited amounts, while albumin, HGF, and several clotting factors are retained. Main characteristic of this process is that a plasma fraction is completely discarded during the filtration procedure. This fraction contains accumulated small molecular weight toxins and free pro-inflammatory cytokines; then, to replace the fluid loss, a mixture composed of electrolyte solution, human albumin solution, and fresh frozen plasma is added to the system and collected to the patient's blood. This SEPET system is designed for use with any commercially available kidney dialysis unit and/or plasma apheresis system utilizing hollow fiber cartridges (Carpentier et al. 2009; Rozga 2006). Many other attempts in developing artificial liver systems are conducted nowadays in order to improve methods and clinical results. The ultimate goal is then to develop a liver support device that will grant patients a substantial survival benefit compared to standard intensive care now available.

Artificial Lung

Loredana De Bartolo and Sabrina Morelli
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

The artificial lung is a medical device used to take over or supplement the function of the lung which is to oxygenate the blood and remove carbon dioxide.

Such a device can replace entirely the pulmonary gas exchange or assist the deficient gas transfer capacity of the natural organ, either temporarily, with the hope that the healing process will eventually repair the diseased organ, or permanently, when irreversible lung damage leaves the patient permanently disabled.

Artificial lung can be used as a bridge to lung transplantation, as a support device immediately post-lung transplant, and as a rescue and/or supplement to mechanical ventilation during the treatment of severe respiratory failure (Diaz-Guzman et al. 2013; Javidfar and Bacchetta 2012).

Current artificial lungs are also known as blood oxygenators and are modules composed of bundles of hollow fiber membranes designed to bring blood and gas phases in intimate contact separated by only the thin walls of the hollow fibers.

Membrane oxygenators can be used in two principal modes: to imitate the function of the lungs in cardiopulmonary bypass (CPB) and to oxygenate blood in longer-term life support, termed extracorporeal membrane oxygenation (ECMO). A membrane oxygenator consists of a thin gas permeable membrane separating the blood and gas flows in the CPB circuit; oxygen diffuses from the gas side into the blood, and carbon dioxide diffuses from the blood into the gas for disposal.

Preliminary efforts to design, fabricate, and test membrane artificial lungs have been reported since the 1950s. The early artificial lungs used relatively impermeable polyethylene or Teflon homogeneous membranes, and when more highly permeable silicone rubber membranes were introduced in the 1960s (and as hollow fibers in 1971), the membrane oxygenator became commercially successful. The introduction of microporous hollow fibers with very low resistance to mass transfer revolutionized the design of membrane modules, as the limiting factor to oxygenator performance became the blood resistance (Martin and Zwischenberger 2013).

Current designs of oxygenator typically use an extraluminal flow regime, where the blood flows outside the gas-filled hollow fibers, for short-term life support, while only the homogeneous membranes are approved for long-term use.

The key design considerations in blood oxygenators include minimizing the resistance to blood flow, reducing the priming volume, ensuring easy debubbling at setup, and minimizing blood activation and thrombogenicity.

The fabrication or wrapping of the fiber bundle in a blood oxygenator can be important as the geometry obtained impacts diffusional boundary layers, secondary flows, and gas exchange efficiency.

Looking ahead, current challenges in bioartificial lung engineering include creation of ideal scaffold materials, differentiation and expansion of lung-specific cell populations, and full maturation of engineered constructs to provide graft longevity after implantation in vivo (Sond and Ott 2012).

Asymmetric Ceramic Hollow Fiber Membranes

Benjamin F. K. Kingsbury
Imperial College London, London, UK

Asymmetric ceramic hollow fiber membranes are ceramic tubes with outer diameters typically ranging from 0.5 to 2 mm, utilized for separation processes. To be classified as asymmetric, a hollow fiber must have a nonuniform cross-sectional structure consisting two or more different morphologies. They may be formed from a wide range of ceramic materials depending on their purpose and may be either dense or porous according to the type of separation process for which they are designed. When combined together in a module, hollow fiber geometry gives rise to extremely high membrane surface area per volume leading to compact membrane module designs. Asymmetric membranes offer improved performance by combining a thin separation layer with a support layer which has high permeability. Although asymmetric structures can be achieved by depositing additional layers on a symmetric ceramic hollow fiber formed by screw

Asymmetric Ceramic Hollow Fiber Membranes, Fig. 1 An asymmetric aluminum oxide hollow fiber micro-filtration membrane with an outer diameter of 1.8 mm

extrusion, the most common method of fabrication involves the incorporation of phase inversion to create asymmetric structures during the extrusion process. In this method, a mixture of polymer binder and ceramic material, suspended in a suitable solvent, is extruded through a spinneret into contact with a fluid that leads to precipitation of the polymer phase. As the polymer binder precipitates, the polymer-ceramic suspension is converted into a polymer-ceramic mixed matrix ceramic hollow fiber precursor. The precursor is then heated to remove the polymer binder and consolidate the ceramic material by sintering to yield the final product. Very small hollow fiber diameters can be achieved using this fabrication technique with asymmetric cross-sectional structures consisting of conical micro-channels as well as a porous ceramic matrix (Fig. 1). Moreover, multiple layers can be extruded simultaneously to form asymmetric cross-sectional structures which also contain layers of different materials.

Asymmetric ceramic hollow fiber membranes can be broadly categorized as either porous or dense. The former operate on a size exclusion basis usually at low to moderate temperatures and are commonly fabricated from inert ceramic materials such as aluminum oxide. Asymmetric structures such as that shown in Fig. 1 (Kingsbury and Li 2009) are prepared in a single step and

consist of a support layer formed from micro-channels and an outer porous separation layer. The development of asymmetric morphologies such as that shown in Fig. 1 allows for filtration membranes with high flux to be fabricated in a cost-effective way, with the additional benefit of integrated separation and support layers, leading to a robust and durable structure. Dense asymmetric ceramic hollow fiber membranes operate at higher temperatures with separation occurring by lattice diffusion. Membranes fabricated from proton conducting, ionic conducting, and mixed ionic and electronic conducting materials have a number of potential applications such as oxygen separation from air, solid oxide fuel cells, and the partial oxidation of methane to synthesis gas. For example, an asymmetric hollow fiber oxygen separation membrane can be formed from a perovskite material, by extruding a hollow fiber in which a region of micro-channels supports a thin outer oxygen separation layer (Zydorczak et al. 2009). The micro-channels formed during the extrusion process provide mechanical strength while at the same time greatly reducing the resistance to oxygen permeation compared to a symmetric hollow fiber structure. Asymmetric multilayer structures formed by co-extrusion have been developed for solid oxide fuel cells and membrane reactor applications in which each layer has a different function. Examples include the co-extrusion of an anode and electrolyte as an asymmetric hollow fiber in a single step (Othman et al. 2010), and the co-extrusion of a dual-layer hollow fiber membrane reactor for partial oxidation of methane to synthesis gas comprised of a dense oxygen separation membrane on a porous catalytically active support (Wu et al. 2011).

Asymmetric Hollow Fiber Membranes

Lan Ying Jiang

School of Metallurgy and Environment, Central South University, Changsha, China

The asymmetric membranes can be formed into different geometries such as the flat sheet and the hollow fibers, by choosing the fabricating or casting equipment. Hollow fibers have annulus cross sections with the inner and outer circular skins of the membranes being concentric. The outer diameter of a hollow fiber is less than 1 mm. Their advantages associated with practice usage include large membrane area per unit volume, self-contained mechanical support, good flexibility, and easy handling during the module fabrication and in the operation, etc. (Matsuura 1994, Peng et al. 2012). These facts have contributed to the lower fabrication cost and higher-performance efficiency of hollow fiber membrane modules.

By far, the most technically used hollow fiber is produced by phase inversion: non-solvent-induced phase inversion (NIPS), (solvent) evaporation-induced phase inversion (EIPS), VIPS (vapor sorption-induced phase inversion), and TIPS (thermally induced phase inversion) (Ulbricht 2006). In single-layer hollow fiber asymmetric membrane formation by NIPS, there are two coagulations taking place in hollow fiber spinning (shell and lumen surfaces), while there is only one major coagulation surface for an asymmetric flat sheet membrane. The mass exchange between internal coagulation liquid and lumen surface for a hollow fiber starts immediately after liquid extrusion from the conduit of a spinneret. For the contact of shell surface of nascent fiber and the external coagulation bath, two

different concepts are used. In some cases, there is an interval between nascent membrane extrusion and immersing in the external coagulant. This contact at the external boundary could also synchronize with that at the internal boundary by directly immersing the spinneret inside the external coagulant. The former has a name of “dry-jet wet spinning.” The mass transfer associated with the dry step during the nascent fiber’s residence time in the air gap is short under commercial spinning conditions but important in membrane structure control. Solvent evaporation in the dry step can cause polymer concentration at dope/air interface increase. This situation is favorable for forming a relatively compact skin and is often practiced in fabricating membranes for gas separation or pervaporation. One can easily create this situation by making the temperature of the spin dope close to the boiling point of the volatile solvent or non-solvent (Jiang et al. 2004). Rheological aspect is another choice in fine-tuning hollow fiber membrane morphological characteristics to meet the requirement of separation tasks. Depending on the polymer intrinsic rheological characteristics, air gap and take-up speed are adjusted to deliver polymer chain orientation or more ordered arrangement along the elongation direction that improves selectivity of gas separation membranes (Kneifel and Peinemann 1992). Shearing effect that occurs inside the spinneret can also induce orientation, which motivates many design strategies of conduit channel near the exit (Widjojo et al. 2007).

Composite hollow fibers are mostly formed by dip coating, interfacial polymerization, etc., as an additional step to the porous hollow fiber formed by phase inversion. Presently, the type of dual-layer composite asymmetric hollow fibers produced by co-extrusion through a triple-orifice spinneret represents a new direction (He et al. 2002). Compared to the single-layer asymmetric hollow fibers, the dual-layer hollow fibers are more advantageous due to the following reasons (Jiang et al. 2009):

1. Material cost saving by more than 95 %
2. Possibility to employ brittle (engineering infeasible) but advanced material

3. By adjusting the dope solution concentration, hollow fibers with ultrahigh pressure resistance can be produced
4. The formation of composite membranes is more straightforward and cost effective
5. Higher fluxes are obtained by circumventing pore penetration occurring in dip coating.

Recently, an idea of immiscibility induced phase separation (I₂PS) was proposed (Ong and Chung 2013). Phase separation of two immiscible dopes renders the formation of a selective layer between the inner layer and outer layer. The degree of swelling of selective layer by feed liquid can be moderated as a result of its being shielded from direct contact with the feed mixture by the outer layer.

Asymmetric Membrane

Lan Ying Jiang

School of Metallurgy and Environment, Central South University, Changsha, China

For almost all the membrane process, flux is one of the essential process parameters. The advantages associated with high flux are small membrane area and efficient system footprint. These two factors are often considered by chemical engineers or managers in their decision-making about setting up processes using membrane separation. The thinner the required membrane structure, the higher the membrane flux. However, mechanical strength will be reduced with decreasing membrane thickness.

One of the solutions to this problem was asymmetric membrane. Loeb and Sourirajan in 1963 (Loeb and Sourirajan 1964) invented integrally skinned asymmetric membrane for reverse osmosis. They are produced by non-solvent-induced liquid-liquid phase separation processes, in which the entire structures are generated in one

step from one material. Phase inversion is a process wherein the thermodynamically stable polymer solution is converted into the instable one by changing dope composition. The resultant membranes exhibit graded morphology with a gradual transition from relative dense structure at one side of the membrane to fully porous structure on the other side, in consistence with the characteristics of phase inversion course. In a simplified manner, this type of membranes is often described as having a thin skin supported by a porous support. The thin skin layer carries out the separation, while the substrate generally presents negligible resistance to the transport of penetrants. This so-called skin layer is nonporous for gas separation, reverse osmosis, pervaporation, and nanofiltration membranes. There also exist several other techniques pertaining to phase inversion. They are thermally or pressure induced. The membranes generated have a rather isotropic cross-section morphology.

To fulfill the same target but avoid the disadvantages of the integrally skinned asymmetric membranes, a series of other types of membrane are developed. Figure 1 shows the schematic of the dense membrane and five principle types of membranes that are currently used (Paul and

Asymmetric Membrane, Fig. 1 Schematic of dense and asymmetric membranes. (a) Dense film, (b) integrally skinned asymmetric, (c) multicomponent ("caulked")

composite, (d) single-layer composite, (e) multilayer composite, (f) asymmetric composite

Yampol'skii 1994): (a) homogeneous dense membrane, (b) integrally skinned asymmetric, (c) caulked, (d) single-layer composite, (e) multilayer composite, and (f) asymmetric composite membranes. Usually, a homogeneous membrane is prepared through solution casting. This type of membrane is used for the lab-scale investigation to fundamentally understand the intrinsic properties of polymers. Various techniques are available in the formation of composite membranes. They can also be categorized as asymmetric membranes morphologically. The multilayer composite (Fig. 1d) is an extension of single-layer composite, and the asymmetric composite (Fig. 1e) is the combination of the integrally skinned asymmetric and composite approaches. In addition to decreasing selective layer thickness, one of the most attractive aspects of the composite membranes is their potential for minimizing materials' cost, because only the selective layer must use a high-performance while more expensive material. The freedom in material choice and membrane formation technique selection with composite membranes facilitates the development of organic/inorganic layered structure that efficiently combines the characteristics of single organic or inorganic material and expands the application area of membrane separation. The aforementioned asymmetric or composite structure can be formed into different geometries such as the flat sheet, the hollow fibers, etc., by appropriately choosing the fabricating or casting equipment.

Today, extensive knowledge exists on how to control the asymmetric membrane's structure including cross-section morphology by the selection of material and membrane formation conditions. The polymeric composite membranes are usually made by solution coating, interfacial polymerization, and plasma polymerization methods on the surface of a prefabricated porous support or by co-extrusion of two or more solutions (Ulbricht 2006). For composite membrane using inorganic materials, they are prepared by various techniques from solvent evaporation, in situ growth from solution, and other alternative methods (Gulianti et al. 2004). The work at commercializing asymmetric membranes, especially those having

nonporous skin, has been hindered by the difficulties of obtaining simultaneously the good selectivity and the high productivity. In other words, the intrinsic property of some advanced material cannot be expressed efficiently in their asymmetric membranes. Various physical or chemical treatments can make the skin layer more perfect (Jiang et al. 2009). One of the breakthroughs conquering this problem in the membrane development was made in 1980s by Henis and Tripodi (Henis and Tripodi 1980). Their invention of coating asymmetric polysulfone membranes with silicon rubber effectively sealed the pinholes and led to first generation of commercial gas separation membrane, Prism or Prism Separator.

Atomic Force Microscopy (AFM)

Nidal Hilal and Daniel Johnson
Centre for Water Advanced Technologies and Environmental Research (CWATER), College of Engineering, Swansea University, Swansea, Wales, UK

The atomic force microscope is a versatile tool increasingly used for the physical characterization of surfaces and is of great interest for the visualization and analysis of process surfaces including

those of membranes used for filtration. It is capable of resolving features from the micrometer down to the subnanometer scale and can operate in air and liquid environments, allowing membranes to be studied in environments matching those encountered during their operation (Hilal et al. 2004; Hilal and Johnson 2010), which allows assessment of effects of, for instance, pH, ionic strength, and effects of additives on membrane structure, a feature not available with other high resolution imaging applications. In addition, the surface needs no special preparation, providing it remains clear of unwanted contamination, and does not need to be electrically conductive, limitations found with some imaging techniques.

The AFM consists of a sharpened probe mounted at the end of a flexible cantilever. The tip of the probe is then used to “feel” the underlying membrane surface, producing a three-dimensional map of the sample topography. There are three basic imaging modes: contact mode, where the tip maintains constant contact with the surface, while feedback loops adjust its height to maintain cantilever deflection and hence force; tapping mode, where the cantilever is vibrated close to the resonant frequency and intermittently contacts the surface with decreased lateral forces compared with contact mode; and noncontact mode in which the probe tip interacts with attractive forces very close to the surface but is kept away from hard repulsive interactions. Noncontact mode is capable of extremely high resolution but is the most difficult to attain in practice. From the imaging data, several quantitative parameters of interest to membrane technologists can be obtained including: surface roughness, pore size, pore-size distribution, as well as showing in fine detail the morphology of fouled and unfouled membrane surfaces and the effects of chemical modification of membrane surfaces (Johnson et al. 2012; Kochkodan et al. 2013). Figure 1 shows a typical image of a cyclopore microfiltration membrane and a resulting pore-size distribution (Bowen et al. 1996; Bowen and Hilal 2009). There are a large number of expansions for AFM instruments allowing many other modes allowing mapping of

Atomic Force Microscopy (AFM), Fig. 1 3D image of cyclopore microfiltration membrane and pore-size distribution for same membrane obtained by AFM

electrical and electrochemical, mechanical, adhesive, frictional and magnetic properties of surfaces of interest.

As well as providing this information, the AFM probe can be used as a force sensor by moving the probe into and out of contact with the sample surface and monitoring deflection in the microcantilever arm. Through careful calibration of the system this deflection can be converted into force, directly measuring the interaction force as a function of probe tip – sample separation distance (Gibson et al. 2004). This allows the detection of DLVO, hydrophobic, hydrostatic and steric interactions, membrane stiffness, and adhesion forces. The sharp tip may be replaced by a colloidal particle, which may be functionalized to simulate any of a number of potential

membrane foulants allowing quantitative measurements of foulant rejection and attachment forces. This makes possible the direct quantification of membrane fouling properties of different materials under a range of environmental conditions and with only a relatively small sample of membrane needed.

Atomistic Simulations Methods

Elena Tocci

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Atomistic Simulations

Atomistic simulations are theoretical and computational modeling tools for interpreting what happens at the atomic scale in solids, liquids, molecules and plasmas. Atomistic simulations,

such as phonon calculations, free-energy optimizations (molecular mechanics), molecular dynamics (MD), Monte Carlo simulations, and crystal structure prediction, are used to interpret existing experimental data and predict new phenomena and to provide a way forward where experiments are not yet possible, e.g., under extreme conditions or at atomistic size- and timescales which are difficult to detect directly (Allen and Tildesley 1989; Haile 1992; Frenkel and Smit 2002; Leach 2001; Brenner 2000; Allen 2004; Tocci and Pullumbi 2011).

Molecular modeling is primarily a tool for calculating the energy of a given molecular structure, and the goal is to understand and model the motion of each atom in the material.

Different levels of atomistic simulations exist, ranging from quantum mechanical models to statistical methods. This means solving numerically the classical or quantum mechanical microscopic equations for the motion of interacting atoms or even deeper – electrons and nuclei.

Quantum mechanical (QM) or *ab initio* methods describe matter at the electronic level, considering the fundamental particles, electrons and protons. The equation from which molecular properties can be derived is the Schrodinger equation, and various approximations must be introduced in order to extend the utility of the method to polyatomic systems.

Atomistic methods are used to compute molecular properties, which do not depend on electronic effects; the whole atom is modeled just as a soft sphere and obeys the laws of statistical mechanics. Atomistic simulation utilizes analytic potential energy expressions (sometimes referred to as empirical or classical potentials) to describe the systems.

The analytic potential energy functions are simplified mathematical expressions that attempt to model interatomic forces arising from the quantum mechanical interaction of electrons and nuclei. Their use is dictated by the need to model systems with sizes and/or timescales that exceed available computing resources, required for quantum calculations, which give no account of the complex electronic structure of atoms.

Forces between atoms are derived from empirical interatomic potentials that are obtained from fitting material properties (e.g., lattice constant, elastic constants, vacancy formation energy, etc.) from experimental data or QM calculations. They may depend on the distance between atoms, angles between bonds, angles between planes, etc.

The general form of the total potential of the N -atom system describes types of interactions, bonded and non-bonded, and can be written as:

$$V(\vec{r}_1, \vec{r}_2, \dots, \vec{r}_N) = \sum V_1(\vec{r}_i) + \sum_{i,j>i} V_2(\vec{r}_i, \vec{r}_j) + \sum_{i,j>i, k>j} V_3(\vec{r}_i, \vec{r}_j, \vec{r}_k) + \dots$$

The part of the potential energy V representing bonding interactions will include terms of the following kind:

$$\begin{aligned} V_{\text{intramolecular}} = & \frac{1}{2} \sum_{\text{bonds}} K_{ij1}^r (r_{ij} - r_{eq})^2 \\ & + \frac{1}{2} \sum_{\substack{\text{bend} \\ \text{angles}}} K_{ijk}^\theta (\theta_{ijk} - \theta_{eq})^2 \\ & + \frac{1}{2} \sum_{\substack{\text{torsion} \\ \text{angles}}} \sum_m K_{ijkl}^{\phi,m} (1 + \cos(m\phi_{ijkl} - \gamma_m)) \end{aligned}$$

The “bonds” typically involve the separation $r_{ij} = |\vec{r}_i - \vec{r}_j|$ between adjacent pairs of atoms in a molecular framework, and a harmonic form with specified equilibrium separation has been used, although this is not the only possible type. The “bend angles” θ_{ijk} are between successive bond vectors such as $\vec{r}_i - \vec{r}_j$ and $\vec{r}_j - \vec{r}_k$ and involve three atom coordinates. Usually this bending term is quadratic in the angular displacement from the equilibrium value, although periodic functions are also used. The “torsion angles” ϕ_{ijkl} are defined in terms of three connected bonds; hence four atomic coordinates are used.

The part of the potential energy V representing non-bonded interactions between atoms is

traditionally split into one-body, two-body, three-body terms:

$$\begin{aligned} V_{\text{non-bonded}}(\vec{r}_1, \vec{r}_2, \dots, \vec{r}_N) \\ = \sum_i v(\vec{r}_i) + \sum_i \sum_{j>i} w(\vec{r}_i, \vec{r}_j) + \dots \end{aligned}$$

The $v(\vec{r}_i)$ term represents an externally applied potential field and describes external force fields (e.g., gravitational field) and external constraining fields (e.g., the “wall function” for particles in a chamber). The pair potential $w(\vec{r}_i, \vec{r}_j) = w(r_{ij})$ neglect three-body (and higher order) interactions.

The Lennard-Jones potential is the most commonly used form:

$$w^{LJ}(r) = 4\epsilon \left[\left(\frac{\sigma}{r} \right)^{12} - \left(\frac{\sigma}{r} \right)^6 \right]$$

where σ is the diameter and ϵ is the depth of the potential energy well. If electrostatic charges are present, the appropriate Coulomb potentials are added:

$$w^{\text{Coulomb}}(r) = \frac{Q_1 Q_2}{4\pi\epsilon_0 r}$$

where Q_1, Q_2 are the charges and ϵ_0 the permittivity of the free space.

To be effective, an analytic potential energy function must possess the following critical properties:

Flexibility: A potential energy function must be sufficiently flexible that it accommodates as wide a range as possible of fitting data.

Accuracy: A potential should be able to accurately reproduce properties of interest as closely as possible.

Transferability: A potential function should be able to study a variety of properties for which it was not fit.

Computational efficiency: Evaluation of the function should be relatively efficient depending on quantities such as system sizes and timescales of interest, as well as available computing resources.

The major methods are molecular mechanics (MM), molecular dynamics (MD), Monte Carlo (MC), and additionally, there is a whole range of hybrid techniques which combine features from both MD and MC methods.

Autothermal Reforming

Fausto Gallucci
Chemical Process Intensification, Department of
Chemical Engineering and Chemistry,
Eindhoven University of Technology, Eindhoven,
The Netherlands

Autothermal reforming or oxidative steam reforming is a combination of conventional

steam reforming of the fuel (endothermic reaction) with the partial oxidation of a small amount of the fuel (exothermic reaction) in order to achieve an autothermal reaction that proceeds without external input of energy (Chang et al. 2010; Tiemersma et al. 2012).

The most studied autothermal reforming is the conversion of methane to hydrogen (Gallucci et al. 2009). The overall chemical reactions taking place in the autothermal reforming of methane include steam reforming (Eq. 1), water gas shift (Eq. 2), and total oxidation (Eq. 3). The energy generated by the oxidation reaction and WGS is used for the SMR:

This reaction system can be carried out efficiently in a membrane reactor as the extraction of hydrogen during the reaction shifts the equilibrium reactions toward completion at moderate temperatures, and thus the extent of oxidation reaction to achieve autothermal reforming is moderate.

One of the problems of autothermal reforming carried out in membrane reactors is the mismatch between the oxidation reaction rate and the reforming reaction rate. The oxidation is often much faster than the reforming, and for this reason in packed bed membrane reactors, a high-temperature region is obtained at the beginning of the bed followed by a low-temperature region at the end of the bed. This could cause problems to the membranes that could be damaged by high temperatures while not working properly (low flux – see Richardson equation) at lower temperatures (Tiemersma et al. 2006; Gallucci et al. 2010).

To circumvent these problems, fluidized bed membrane reactors are often proposed for this kind of reaction system, as the solid circulation inside the reactor allows a virtually isothermal condition even in case of highly exothermic reactions.

Examples of autothermal reforming (ATR) (or oxidative steam reforming) reactions also include the ATR of ethanol and methanol or the ATR of naphtha (Lin et al. 2010; Tosti et al. 2010; Moreno and Wilhite 2009). All these reactions have been successfully tested in membrane reactors for pure hydrogen production.

Azeotropic Distillation

Alessandra Criscuoli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Azeotropic distillation is a particular type of distillation by which it is possible to separate azeotropes (Perry and Green 1984). Azeotropes are mixtures of two or more substances that boil together at a constant temperature. It is, therefore, impossible to separate them directly by distillation, because a distillate of the same composition of the liquid feed is produced. Azeotropic distillation is based on the addition of a compound that acts on the volatility of the substances contained into the azeotrope, so that a new azeotrope, made of the substances present in the starting azeotrope and the added compound, is formed. The new azeotrope can be, then, removed by distillation, and a residual highly rich in one of the substances is obtained. A typical example is the distillation of mixtures of water-ethanol. By classic distillation, the distillate contains 95 % of alcohol (pure boiling temperature, 78.4 °C) and 5 % of water (pure boiling temperature, 100 °C), and no further increments in ethanol purity can be reached, because this mixture boils, as a unique compound, at 78.17 °C. However, if benzene or cyclohexane is added to the mixture, a ternary azeotrope is formed that incorporates all the water and has a lower boiling point than ethanol. Therefore, if the distillation is now carried out, the new azeotrope will be recovered as distillate, while practically pure ethanol is produced as residue (see Fig. 1). Besides

A

Azeotropic Distillation, Fig. 1 Azeotropic distillation of water-ethanol

azeotropic distillation, other methods can be also employed for the separation of azeotropes and, in particular, membrane operations like pervaporation and membrane distillation.

β -Lactoglobulin and α -Lactalbumin Separation

Andrew L. Zydney

Department of Chemical Engineering, The
Pennsylvania State University, University Park,
PA, USA

β -Lactoglobulin and α -lactalbumin are the two dominant proteins in whey (see Table 1). Although whey protein concentrates are used as food additives in the production of a variety of dairy products, meats, and beverages, the unique nutritional, therapeutic, and functional characteristics of the individual whey proteins are largely unrealized in these whey products. There has thus been considerable commercial interest in the separation of β -lactoglobulin and α -lactalbumin to take advantage of their functional and biological properties. α -Lactalbumin is attractive as a nutraceutical because of its high tryptophan content (Cayot and Lorient 1997). α -Lactalbumin also provides enhanced whippability in meringue-like formulations and may have potential as a contraceptive agent. β -Lactoglobulin is an effective foam

stabilizer and can be used in the production of confections (Cayot and Lorient 1997).

There are two types of membrane systems that have been explored for the separation of β -lactoglobulin and α -lactalbumin: ultrafiltration and membrane adsorbers (also referred to as membrane chromatography). Cheang and Zydney (2003) demonstrated that β -lactoglobulin and α -lactalbumin could be separated using commercial ultrafiltration membranes by adjusting the solution pH and ionic strength to enhance the selectivity. These results were subsequently extended to purify β -lactoglobulin and α -lactalbumin from a whey protein isolate using a two-stage ultrafiltration process (Cheang and Zydney 2004).

Membrane chromatography is of potential interest for the separation of β -lactoglobulin and α -lactalbumin due to the high flow rates that can be achieved in these systems. For example, Saufi and Fee (2011) examined the use of a mixed mode membrane chromatography system containing both cation and anion exchange sites for the fractionation of whey proteins. β -Lactoglobulin was preferentially bound to the membrane, with the α -lactalbumin collected in the flow through.

β -Lactoglobulin and Alpha-Lactalbumin Separation, Table 1 Physical characteristics of major whey proteins (From Zydney 1998)

Protein	Concentration (g/L)	Molecular weight (g/mol)	Isoelectric pH
β -Lactoglobulin	2.7	18,362	5.2
α -Lactalbumin	1.2	14,147	4.5–4.8
Immunoglobulins	0.65	150,000–1,000,000	5.5–8.3
Bovine serum albumin	0.4	69,000	4.7–4.9
Lactoferrin	0.1	78,000	9.0
Lactoperoxidase	0.02	89,000	9.5
Glycomacropeptide		7

Backwashing

Onita D. Basu

Department of Civil and Environmental Engineering, Carleton University, Ottawa, Canada

Backwashing of a membrane refers to the reversal of flow through a membrane system in comparison to the normal flow direction required for permeate production. The purpose of backwashing is to assist with removing or loosening foulants from the membrane surface and within the membrane pores to control membrane fouling. It is a fundamental membrane operational step to control the rate of transmembrane pressure (TMP) increase over time. Backwashing is utilized with low

pressure membrane systems, i.e., microfiltration and ultrafiltration, while high pressure membrane systems, i.e., nanofiltration and reverse osmosis, do not employ backwashing to control fouling. Backwashing is most commonly initiated on a timed cycle; however, it may also be initiated on a transmembrane pressure set point or a volume filtered set point (AWWA 2013). Backwashing is performed in stages through a membrane plant in order to ensure that water is being produced at all times; in other words, there is rotation through which individual membrane units will be backwashed, while the majority, at any given time, are still maintained in operation. When backwashing is no longer considered effective at controlling membrane fouling, as indicated by a set point loss in flux, permeate production, or high TMP value, the membrane system will undergo chemical cleaning. Additionally, a chemically enhanced backwash (CEB) may be put in place before a membrane unit is taken off-line for a full chemical clean. In the event of a CEB, an oxidant, such as chlorine, and acids or bases, such as citric acid or sodium hydroxide, are added to the backwash water to assist in the removal of foulants from the membrane pores and membrane surface.

Backwashing has been found to be helpful in removing cake layer fouling that is particulate in nature. However, research has shown that backwashing alone does not remove the majority of the cake layer fouling but instead mainly increases its porosity, effectively loosening the cake layer against the membrane surface (Ye et al. 2011). Therefore, it is important to include an air scour or cross-flow velocity step with backwashing to effectively decrease the size

and thickness of the cake layer foulants on the membrane surface (Remize et al. 2010). However, it is important to keep in mind that pore blocking results in a faster deterioration of the membrane flux and is more likely to lead to irreversible fouling than cake layer fouling. The cake layer itself can prevent pore blocking by acting like a prefilter for the membrane surface. Thus, if too much of the cake layer is removed, the membrane system will have a faster development of pore blocking over several cycles of backwashing. As such it is important to configure an optimized backwash procedure with associated air scour or cross-flow velocity step for a particular membrane and water type. When optimizing a system, it is important to note that research has found that backwash duration and backwash flux at low rates, equal to or less than the permeate flux, are not likely to have an impact on fouling rate in low fouling systems, although backwash duration was found to have an optimum value associated with net permeate production (Akhondi et al. 2014). Other research has shown that too high of a backwash flux may actually exacerbate fouling by potentially removing too much of the cake layer and resulting in more irreversible pore fouling occurring (Wu et al. 2008). Given that backwashing has been shown to clearly assist in controlling fouling, it is important for all membrane plants to monitor the effectiveness of their backwash procedures on a regular basis with consideration for changes in water quality over different seasons.

Backwashing Frequency

Onita D. Basu

Department of Civil and Environmental Engineering, Carleton University, Ottawa, Canada

Optimization of backwash frequency is an important consideration in terms of membrane operation as it uses produced water for the backwash cycle; therefore, the more frequent the backwash, the lower the efficiency of the membrane system overall in terms of produced water. In addition to the backwash frequency, which is generally every 30–90 min, consideration should also be applied for backwash duration and backwash flux. Backwash duration is how long a membrane system is backwashed and is typically between 1 and 3 min. In some cases, backpulsing may also be used, and this term refers to short burst cycles for reversing the flow through the membrane that generally last between 0.5 and 5 s. Backwash flux is the fluid flow rate through the membrane, and it is generally equal to the initial operating permeate flux of the membrane system, although it may be higher. Backwash frequency is linked to the operating membrane flux, with a lower flux resulting in a lower required backwash frequency, while a higher flux tends to require a higher backwash frequency (Wang et al. 2008; Raffin et al. 2011).

Backwashing is often considered to control reversible fouling; however, it is also tied to the control of irreversible fouling as well. Research has demonstrated, for instance, that while backwash frequency may not appear to impact on the rate of reversible fouling, it can influence the rate of irreversible fouling. Specifically, longer periods between backwashes (i.e., 60 min vs. 30 min)

resulted in an increase in the irreversible fouling rate (Raffin et al. 2012). The importance of this information is that higher irreversible fouling rates result in higher frequencies of chemical cleaning for a membrane system, which has both an adverse impact on water production and the economics of running a membrane system. Of course, consideration must be taken for the loss of system productivity when increasing the frequency of backwashing as well. As backwash frequency increases, the membrane productivity is concomitantly decreasing; backwashing can result in upwards of a 10 % loss in membrane productivity. It is, therefore, important to weigh out the benefits and losses associated with increasing backwashing frequency and losing productivity versus decreasing the backwash frequency and potentially increasing the required chemical cleaning of the membrane system.

Bacteria and Spore Removal

Karin Schroen

Laboratory of Food Process Engineering,
Wageningen University and Research Centre,
Wageningen, The Netherlands

Bacteria can be of great influence on many processes, be it in, for example, food, pharma, fermentation, or water production. Obviously, bacteria (and their spores) can be removed by heat treatment or addition of specific components that inhibit their growth or even kill them, but the

downside of this is that the product properties will be influenced and this is mostly undesirable. In this respect, membrane microfiltration could be an interesting alternative when used for cold sterilization. If the bacterial count is not too high and other components are sufficiently smaller, the removal of bacteria and spores can rather easily be carried out using dead-end microfiltration.

When the size of bacteria and other components overlap, this separation is far from straightforward. An illustrative example can be found in dairy separation, in which cold sterilization of “milk” has been reported. The components that are most important for this separation are the milk fat globules (cream; typical sizes from 0.1 to 15 μm), bacteria (0.5–5 μm), and casein micelles (20–300 nm). Since cream and bacteria overlap in size, the cream is first removed by centrifugation. The resulting skim milk receives the cold sterilization treatment. Various researchers have investigated how far the bacterial count could be reduced as listed in Table 1.

From the table, it is clear that a variety of membranes and process conditions have been used, ranging from very high to low cross-flow velocities, and application of a uniform transmembrane pressure or frequent back pulsing. These conditions are clearly aiming at processing under very different conditions, where frequent back pulsing will control the amount of deposited material, the uniform transmembrane pressure concept aims at stable filtration conditions along the length of the membrane. All approaches have shown interesting results; the log reductions that can be achieved are around 4 (10,000-fold reduction), although it should be noted that these values are not as high as obtained after regular heat treatment.

The highest log reduction (6.6, which is higher than for regular pasteurization) was claimed for microsieves, which are silicon plates with very uniform pores prepared by laser interference lithography (Van Rijn and Elwenspoek 1995). Although the bacterial reduction was measured for dead-end filtration using a 0.5 μm microsieve and SMUF (simulated ultrafiltrate) spiked with *Bacillus subtilis*, it is expected that the high log

Bacteria and Spore Removal, Table 1 Comparison of cold sterilization results from various sources

Membrane type and flux	Process conditions cross-flow/pressure, UTP, back pulsing	Log reduction	Source
Ceramic 1.4 μm; 1.4•10 ⁻⁴ m/s	50 kPa, 7.2 m/s UTP, skim milk	Above 3.5	Saboya and Maubois 2000
Reversed asymmetric 0.87 μm; 1.4•10 ⁻⁴ m/s	0.5–1 m/s; back pulsing frequency 0.2–1 s ⁻¹ , skim milk	Between 4 and 5	Guerra et al. 1997
Microsieve 0.5 μm	Dead-end filtration of spiked SMUF	6.6	Van Rijn and Kromkamp 2001
Bactocatch: ceramic membranes	6–8 m/s, skim milk, UTP		Holm et al. 1989

count reduction is a result of its narrow pore size distribution of the microsieve.

In case of the uniform transmembrane pressure concept, reduction of bacteria and spores by microfiltration is carried out near the critical pressure, at which the amount of particles that is carried toward that membrane by permeate is counterbalanced by the amount of particles diffusing away from the membrane to the feed solution. We expect that this can be even taken one step further, as indicated in the work of van Dinther et al. (2011), in which particles that size-wise correspond to milk fat globules and bacteria were reported to be separated by fluid skimming and lift effects. For this to occur, first a nonporous channel is used to induce particle migration after which in a porous area the small particles that are situated close to the wall can specifically be removed. This process has not been demonstrated at large scale, but it holds great promise since it would allow for direct separation of bacteria from full milk without the need of centrifugation. Besides, the separation is no longer determined by the pore size of the membrane; metal sieves from SPG Veco with uniform pores of around 20 μm were used, but by the process conditions that determine which part of the feed is removed.

Synonyms

Bacterial biofilm; Bacterial adhesion; Biofouling

Biofilms were observed as early as 1674, when Antonie van Leeuwenhoek used his primitive but effective microscope to describe aggregates of “animalcules” that he scraped from human tooth surface (Costerton 1999). Since then, more accurate descriptions of biofilms are made. Bacteria generally exist in one of two types of population: planktonic, freely existing in bulk solution, and sessile, as a unit attached to a surface or within the confines of a biofilm (Garrett et al. 2008).

Biofilm is a result of many complicated steps. It includes the formation of a conditioning film on a material's surface, the movement of bacteria, an attachment process, the growth on material surfaces, and the breakdown finally. For bacteria, the advantages of biofilm formation are numerous. These advantages include: protection from antibiotics (Godberg 2002), disinfectants (Peng et al. 2002), and dynamic environments (Chen et al. 1998).

Over the past few decades, biofilm growth has been observed in many industrial and domestic domains. Many industries suffer the ill effects of biofilm growth of one type or another, which can result in heavy costs in cleaning and maintenance. Biofilms occurring in membrane systems may cause severe loss performance and the use of costly cleaning procedures to maintain output and quality. The fouling is often so severe that acceptable operation cannot be maintained and membrane replacements are needed. It is necessary to understand the biofilm formation mechanism with the aim to propose a solution to contrast this fouling.

Bacteria are capable of colonizing almost any surface and have been found at extreme conditions such as temperatures from -12°C to 110°C and pH values between 0.5 and 13.

Biofilm growth occurs by physical, chemical, and biological processes. Fletcher described the accumulation of microorganisms on a collecting surface as a process of three stages: (i) adsorption, or the accumulation of an organism on a collector surface, i.e., substrate (deposition); (ii) attachment, or the consolidation of the interface between an organism and a collector, often involving the formation of polymer bridges between the organism and collector; and (iii) colonization, or growth and division of organisms on

the collector's surface. Although useful as a snapshot of biofilm growth, this type of profile is limited when considering the intimate processes of cell–substrate/cell–cell interaction. Characklis and Marshal later described an eight-step process which included the formation of an initial conditioning layer, reversible and irreversible adhesion of bacteria, and the eventual detachment of cells from a mature biofilm for subsequent colonization.

Anything that may be present within the bulk fluid can through gravitational force or movement of flow settle onto a substrate and become part of a conditioning layer. This layer modifies substrata facilitating accessibility to bacteria. Surface charge, potential, and tensions can be altered favorably by the interactions between the conditioning layer and substrate. The substrate provides anchorage and nutrients augmenting growth of the bacterial community.

Initially, planktonic microbial cells are transported from bulk liquid to the conditioned surface either by physical forces or by bacterial appendages such as flagella. The reversible adsorption of a fraction of the cells reaching the surface normally occurs. Local environmental variables which contribute to bacterial adhesion are factors such as available energy, surface functionality, bacterial orientation, temperature, and pressure conditions. If repulsive forces are greater than the attractive forces, the bacteria will detach from the surface. The probability of this phenomenon occurs is higher before the formation of the conditioning layer. The activation energy for desorption of bacteria is low and so it is likely to occur, underlining the weakness of the bonds. Physical forces associated to bacterial adhesion include the van der Waals forces, steric interactions, and electrostatic (double layer) interaction, collectively known as the DVLO (Derjaguin, Verwey, Landau, and Overbeek) forces, which originally described the interaction of a colloidal particle with a surface (Rutter and Vincent 1980). According to this theory, the total interaction between a surface and a particle is the summation of their van der Waals and Coulomb interactions. Since the van der Waals attractive force is dominant in the vicinity of a surface, particles adhere

irreversibly because they cannot separate from the surface by Brownian motion. In contrast, the Coulomb interaction becomes dominant at a distance away from the surface because the van der Waals force decreases sharply with distance. Other interactions that DVLO theory takes into consideration are hydrophobic–hydrophilic and osmotic (Chang and Chang 2002) and have also been described in terms of thermodynamic interaction (Gallardo-Moreno et al. 2002).

In real time, a number of the reversibly adsorbed cells remain immobilized and become irreversibly adsorbed. It has been argued that the physical appendages of bacteria (flagella, fimbriae, and pili) overcome the physical repulsive forces of the electrical double layer (De Weger 1987). Subsequently, the appendages make contact with the bulk lattice of the conditioning layer stimulating chemical reactions such as oxidation and hydration and consolidating the bacteria–surface bond. Some evidence has shown that microbial adhesion strongly depends on the hydrophobic–hydrophilic properties of interacting surfaces (Liu et al. 2004).

As the stationary cells divide (binary division), daughter cells spread outward and upward from the attachment point to form clusters. Typically, such interactions and growth within the developing biofilm form into a mushroom-like structure. This structure is believed to allow the passage of nutrients to bacteria deep within a biofilm. After an initial stage, a rapid increase in population is observed, otherwise described as the exponential growth phase. This depends on the nature of the environment, both physically and chemically. The rapid growth occurs at the expense of the surrounding nutrients from the bulk fluid and the substrate. At this stage the physical and chemical contribution to the initial attachment ends and the biological processes begin to dominate. Excretion of polysaccharide intercellular adhesin (PIA) polymers and the presence of divalent cations interact to form stronger bonding between cells (Dunne 2002).

Differential gene expression between the two bacterial states (planktonic/sessile) is in part associated to the adhesive needs of the population. For example, the production of surface appendages is

inhibited in sessile species as motility is restricted and no longer necessary. Simultaneously, expression of a number of genes for the production of cell surface proteins and excretion products increases. Surface proteins (porins), such as Opr C and Opr E, allow the transport of extracellular products into the cell and excretion materials out of the cell, e.g., polysaccharides (Hancock et al. 1990). The structure of many Gram-negative bacterial polysaccharides is relatively simple, comprising either homopolysaccharides or heteropolysaccharides (Sutherland 2001). These molecules impart mechanical stability and are pivotal to biofilm adhesion and cohesion and evasion from harsh dynamic environmental conditions. They consolidate the biofilm structure. Hall-Stoodley and Stoodley identified the differences in gene expression of planktonic and sessile cells, and as many as 57 biofilm-associated proteins were not found in the planktonic profile.

The stationary phase of growth describes a phase where the rate of cell division equals the rate of cell death. At high cell concentration, a series of cell signaling mechanisms are employed by the biofilm, and this is collectively termed quorum sensing (Bassler 1999). Quorum sensing describes a process where a number of autoinducers (chemical and peptide signals in high concentrations, e.g., homoserine lactones) are used to stimulate genetic expression of both mechanical and enzymatic processors of alginates, which form a fundamental part of the extracellular matrix. The death phase sees the breakdown of the biofilm. Enzymes are produced by the community itself which break down polysaccharides holding the biofilm together, actively releasing surface bacteria for colonization of fresh substrates. Alginate lyase produced by *Pseudomonas fluorescens* and *Pseudomonas aeruginosa*, N-acetyl-heparosan lyase by *Escherichia coli*, and hyaluronidase by *Streptococcus equi* are examples of the enzymes used in the breakdown of the biofilm matrix (Sutherland 1999). Simultaneously, the operons coding for flagella proteins are upregulated so that the organisms have the apparatus for motility and the genes coding for a number of porins are downregulated, thus

completing a genetic cycle for biofilm adhesion and cohesion.

Changes in pH can have a marked effect on bacterial growth and as such are frequently exploited in the production of detergents and disinfectants used to kill bacteria. Bacteria possess membrane-bound proton pumps which extrude protons from the cytoplasm to generate a transmembrane electrochemical gradient (Rowland 2003), i.e., the proton motive force. The passive influx of protons in response to the proton motive force can be a problem for cells attempting to regulate their cytoplasmic pH (Booth 1985). Large variations in external pH can overwhelm such mechanisms and have a biocidal effect on the microorganisms. Bacteria respond to changes in internal and external pH by adjusting the activity and synthesis of proteins associated with many different cellular processes (Olsen 1993). Studies have shown that a gradual increase in acidity increases the chances of cell survival in comparison to a sudden increase by rapid addition of HCl (Li 2001). This suggests that bacteria contain mechanisms in place which allow the bacterial population to adapt to small environmental changes in pH. However, there are cellular processes which do not adapt to pH fluctuations so easily. One such process is the excretion of exopolymeric substances (polysaccharides). Optimum pH for polysaccharide production depends on the individual species, but it is around pH 7 for most bacteria.

Both mixed species and pure culture biofilms behave like viscoelastic fluids. Biofilms exhibit both irreversible viscous deformation and reversible elastic response and recoil (Ohashi and Harada 2004). Extracellular polymeric substances like alginate, xanthan, and gellan gum aggregate due to hydrogen bonding to form highly hydrated viscoelastic gels (Stoodley et al. 1999). The presence of acetylated uronic acids in the bacterial alginate of *P. aeruginosa* biofilms increases its hydration capacity. These properties provide the biofilm with mechanical stability (Stoodley et al. 2002).

The matrix formed by EPS responds to stress by exhibiting (i) elastic tension due to a combination of polymeric entanglement, entropic, and

weak hydrogen bonding forces; (ii) viscous damping due to polymeric friction and hydrogen bond breakage; and (iii) alignment of the polymers in the shear direction (Klapper et al. 2002). Such properties change with increased temperature. Increasing the temperature of polysaccharides produces a gel-like substance which gradually increases in strength until a critical point is reached. At the critical point the gel forms a solution (Villain-Simonnet et al. 2000). Such behavior affects the viscosity of the polysaccharides which can affect biofilm adherence. The optimum temperature for a microorganism is associated with an increase in nutrient intake resulting in a rapid formation of biofilm (Stepanovic et al. 2003). Enzymes are responsible of nutrient metabolism; then the formation of a biofilm is dependent on the presence and reaction rates of enzymes. Temperature influences the reaction rate of enzymes having an impact on the development of the cells. Optimum temperatures result in the healthy growth of bacterial populations. Temperatures away from the optimum negatively influence bacterial enzyme reaction rates, and a reduction of bacterial growth efficiency occurs. Fletcher reported the effect of temperature on attachment of stationary phase cells. Findings showed that a decrease in temperature reduced the adhesive properties of a marine *Pseudomonad*. It is believed that the effect was due to a decrease in the bacterial surface polymer at lower temperatures as well as effects such as reduced surface area. However, Herald and Zottola observed that the presence of bacterial surface appendages was dependent on temperature. At 35 °C cells were shown to have a single flagellum, while at 21 °C they had two to three flagella, and at 10 °C, cells exhibited several flagella. This may suggest that the initial interaction between the bacteria and substrate may increase with a lowering of temperature, increasing the likelihood of adhesion. Perhaps the more uniform properties of polysaccharides at lower temperatures increase the possibility of biofilm adhesion, because many microbial polysaccharides undergo transition from an ordered state at lower temperatures and in the presence of ions to a disordered

state at elevated temperature under low ionic environments (Nisbet et al. 1984).

Although there is plenty of information describing the effect of temperature on bacterial growth in culture, the effect of temperature on the removal of adhered microorganisms is not so well documented. The reports available describe fairly radical effects of temperature on adhered bacteria. Marion-Ferey et al. observed the effect of high temperatures (80–90 °C) on the removal of biofilms. It was discovered that these temperatures were not effective for biofilm removal due to “baking effects” at high temperature, apparently increasing the adherent nature of the biofilm to the surface.

Barium Sulfate (BaSO₄), Fouling due to

Alice Antony and Pierre Le-Clech
School of Chemical Engineering, The University of New South Wales, UNESCO Centre for Membrane Science and Technology, Sydney, NSW, Australia

Barium sulfate or barite, BaSO₄ is a nonalkaline scale, particularly problematic in membrane systems due to its extremely low solubility, 10⁻⁵ mol/l (equivalent to 2.33 mg/l) in pure water. Also, this scale is extremely difficult to remove and clean from membrane surfaces if not detected at an early stage and is allowed to age into a hard adherent layer. BaSO₄ could originate from various sources. In the offshore oil industry for example, seawater (containing high level of sulfate) is

injected into reservoirs, and the resulting mixture generally features stable supersaturated BaSO₄, ready to precipitate. While alkaline scales can be controlled by altering the feed pH prior to filtration, sulfate scales are insensitive to pH and therefore cannot be controlled by acid addition. BaSO₄ scales are usually needle shape crystals which can easily damage the active layer of the membrane, resulting in loss of integrity (Fig. 1).

Du Pont method is widely applied as prediction method for BaSO₄ scale in RO systems using the salt solubility at 25 °C and the solubility product, K_c (Boerlage 2001). The K_c expresses the dynamic equilibrium between the scalant crystal ions in solution and the crystal solid phase, for example, the K_c for BaSO₄ is expressed as:

$$K_c = [Ba^{2+}][SO_4^{2-}] \quad (\text{at equilibrium})$$

K_c is determined graphically as a function of ionic strength for the desired recovery (Boerlage et al. 1999). The relationship between K_c and ionic strength is derived from data on the effect of individual monovalent and divalent cations on barium solubility. When the scalant concentration product exceeds K_c, the solution is supersaturated and scaling may occur. Du Pont recommends a recovery such that the scalant concentration product is 20 % below the K_c to prevent scaling. This ensures a safety factor for concentration polarization which may occur at the membrane surface,

Barium Sulfate (BaSO₄), Fouling due to, Fig. 1 SEM-EDS images showing BaSO₄ scaling on RO membrane treating cooling water from power plant (Picture provided by Dr Alice Antony, The University of New South Wales, Australia)

causing a higher localized concentration than in the bulk solution (Boerlage 2001). The major limitation of this index is that it lacks background information on interactions between ionic species on saturation concentrations; as a result, it also neglects the effects of common and uncommon ions on solubility of scale forming species and the interactions between ionic species.

Addition of antiscalant is the common method to control the BaSO_4 scale formation. However, continuous monitoring of the RO performances through conventional techniques lacks the sensitivity to detect the subtle changes occurring across the membrane, and in particular, early deposition of BaSO_4 . This lack of detailed and timely assessment of the fouling state can result in delay in applying the necessary cleaning strategies, whose efficiency is limited for fully developed BaSO_4 scaling layers, known to be particularly resistant to conventional cleaning methods. When BaSO_4 scaling is observed during autopsy analysis, crown ethers and concentrated sulphuric acid are generally recommended as cleaning agents, causing partial membrane hydrolysis (Van der Leeden 1991). Alkaline chelants have also been reported to be efficient cleaning agents (Chesters 2009).

Basic Electrochemical Relations in Membrane Processes: Electron Conductivity, Ion Conductivity, Ohm's Law, and Coulomb's Law

Lidietta Giorno¹ and Heiner Strathmann²

¹Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

²Universität Stuttgart, Institute of Chemical Process Engineering Stuttgart, Baden-Württemberg, Germany

In certain membrane processes, charged components such as salt solutions are separated by neutral membranes or membrane carrying fixed positive or negative charges using an electrical potential as driving force. The behavior of ions in solution and in a membrane is rather different from that of uncharged components because of the strong interaction of electrical charges with each other and their surrounding. Therefore some fundamental electrochemical relations shall be briefly reviewed.

Electron and Ion Conductivity and Ohm's Law

The transport of electric charges, i.e., an electric current, can be achieved by two characteristic modes (Kortüm 1957), i.e., by:

- Transport of electrons through solid material such as metals
- Transport of ions through liquids such as electrolyte solutions

The conductivity of electrons, i.e., metal conductors, is generally three to five orders of magnitude higher than the conductivity of electrolyte solutions. Furthermore, the conductivity of metals is decreasing with increasing temperature, while the conductivity of electrolyte solutions is increasing with the temperature. The most important difference between electron and ion conductivity,

however, is the fact that ion conductivity is always coupled with a transport of mass, while due to the very small mass of an electron virtually no mass is transported in an electron conductor. In spite of the basic difference in the transport mode between electron and ion conductivity, the electrical current can be described in both cases by the same mathematical relation which states that the electrical current is proportional to the electrical potential driving force. This relation is referred to as Ohm's law which is given by

$$\varphi = RI \quad (1)$$

Here φ is the electrical potential between two electron sources, e.g., between two electrodes in an electrolyte solution expressed in Volt, I is the electrical current between the electron sources expressed in ampere, and R is the electrical resistance expressed in ohm.

The resistance R is a function of the specific resistance of the material, the distance between the electron sources, and the cross-section area of the material through which the electric current passes. It is given by

$$R = \rho \frac{l}{q} \quad (2)$$

Here R is the overall resistance, ρ is the specific resistance, l is the length, and q is the cross-section area of the conducting material.

The reversal of the resistance and of the specific resistance, respectively, is the conductivity and the specific conductivity and thus is

$$S = \frac{1}{R} \text{ and } \kappa = \frac{1}{\rho} \quad (3)$$

Here S is the conductivity and κ is the specific conductivity.

The conductivity of electrolyte solutions depends on the concentration and the valence of the ions in the solution. It is expressed as the equivalent conductivity or molar conductivity (Harned and Owen 1958). For a solution of a single electrolyte, the equivalent conductivity is given by

$$\Lambda_{eq} = \frac{\kappa}{C(z_a v_a + z_c v_c)} \quad (4)$$

Here Λ_{eq} is the equivalent conductivity of an electrolyte; C is the molar concentration of the electrolyte in the solution; z_a and z_c are the charge numbers of the anion and cation, respectively; and v_a and v_c are the stoichiometric coefficients of the anion and cation, respectively.

The stoichiometric coefficient gives the number of anions and cations in a mole electrolyte, and the valence gives the number of charges related to an ion. For example, for NaCl v_c and v_a are identical and 1 and also z_a and z_c are 1. However, for MgCl_2 v_c is 1 and v_a is 2, and z_c is 2 and z_a is 1.

The equivalent conductivity can be expressed as the sum of the contributions from its individual ions. Thus

$$\Lambda_{eq} = \lambda_a + \lambda_c \quad (5)$$

Here Λ_{eq} is the equivalent conductivity and λ_a and λ_c are the equivalent conductivities of anion and cation, respectively.

The electrical current passing through an electrolyte solution under the driving force of an electrical potential gradient is proportional to the concentration of the ions in the solution, the stoichiometric coefficients for cat- and anions, and the number of electrical charges carried by one ion, i.e., its valence and the ion mobility in the electrolyte solution. The number of electrical charges carried by all ions of an electrolyte under the driving force of an electrical potential gradient through a certain area A is given by

$$J_e = \sum_i z_i u_i v_i C e N_A \Delta\varphi = \sum_i z_i F J_i \quad (6)$$

Here J_e is the flux of electrical charges and J_i that of the individual ions; z , u , and v are the charge number, the ion mobility, and the stoichiometric coefficient, respectively; C is the concentration of the electrolyte; e is the charge of an electron, N_A the Avogadro number, φ an electrical potential, and the subscript i refers to the ions in the solution; and F is the Faraday constant.

The ion mobility u has the dimension $\text{m}^2\text{s}^{-1}\text{V}^{-1}$. The charge of an electron is $e = 1.6019 \times 10^{-19}$ C, and the Avogadro number is $N_A = 6.0232 \times 10^{23}$ molecules per mol or in this case electrical charges per mole. The product of e and N_A is called the Faraday constant which is $F = 96,485$ C eq^{-1} (Atkins 1990).

The flux of electrical charges represents an electrical current, which is for a solution of a single electrolyte according to Ohm's law given by

$$I = \frac{U}{R} = \sum_i z_i F J_i A = \frac{\sum_i z_i u_i v_i C F A \Delta\varphi}{l} \quad (7)$$

Here I is the current, U is the applied voltage, R is the resistance, A is the area through which the current passes, $\Delta\varphi$ is the voltage difference between two points, and l is the distance between the two points.

Coulomb's Law and the Electric Field Effect on Ions in Solution

Electrical charges carried by ions interact with each other. Opposite charges attract each other and identical charges repel each other. The interaction force between two point electrical charges q_1 and q_2 in a vacuum separated by a distance r is given by

$$K = \frac{q_1 q_2}{4\pi\epsilon_0 r^2} \quad (8)$$

Here K is the interaction force between two point electrical charges, q_1 and q_2 are electrical charges, r is the distance between the two point electrical charges, and ϵ_0 is the permittivity of vacuum.

Equation 8 is referred to as Coulomb's law and the electrical charge is expressed in Coulomb.

The permittivity depends on the medium between the electrical charges. In a vacuum the permittivity is a fundamental constant denoted as ϵ_0 . It has the value 8.854×10^{-12} $[\text{C}^2 \text{J}^{-1} \text{m}^{-1}]$. If the medium is not a vacuum, the permittivity can

be expressed in terms of a relative permittivity ϵ_r which is also referred to as dielectric constant of the medium (Atkins 1990). It is given by

$$\epsilon_r = \frac{\epsilon}{\epsilon_0} \quad (9)$$

Here ϵ , ϵ_r , and ϵ_0 are the permittivity of a medium, the relative permittivity, and the permittivity in the vacuum, respectively.

Coulomb's law describes the interaction between two point charges. In some cases it is desirable to know the force exerted by one charge q in a certain distance r to its surrounding. This force is referred to as electric field. It is given by

$$E = \frac{K}{q} \quad (10)$$

Here K is the force, E is the electric field, and q is an electrical charge.

In determining the electric field, the direction of the field must be taken into account. For a point electrical charge q , the electric field is radial symmetric (Starzak 1984; Kortüm 1957) and given by

$$E = \frac{q}{4\pi\epsilon r^2} \quad (11)$$

Here E is the electric field around a point electric charge q , r is the distance from the electrical charge, and ϵ is the permittivity of the media surrounding the charge. The electric field has the units of newton per Coulomb or volt per distance.

The electric field around a point charge is illustrated in Fig. 1a, which shows the field strength or field density symbolized by density of the lines which is decreasing with the distance from the point charge. The electric field between two point charges of opposite charge is illustrated in Fig. 1b. In this case the two charges will attract each other. If they carry the same charge, they will repulse each other.

The electric field can be expressed by an electrical potential gradient. If the electrical potential varies over a certain distance, the electric field associated with this potential is given by the

Basic Electrochemical Relations in Membrane Processes: Electron Conductivity, Ion Conductivity, Ohm's Law, and Coulomb's Law,

Fig. 1 Schematic drawing illustrating the electric field lines (a) around a point charge and (b) between a positive and a negative point charge

Basic Electrochemical Relations in Membrane Processes: Electron Conductivity, Ion Conductivity, Ohm's Law, and Coulomb's Law, Fig. 2 Schematic drawing illustrating (a) the distribution of counterions

around a center-ion and (b) the potential and the concentration of excess charges around a center-ion as function of distance

derivative in the direction of the electric field (Kortüm 1957):

$$\operatorname{div} E = -\operatorname{div} \operatorname{grad} \varphi = \frac{4\pi}{\epsilon} \rho \quad (12)$$

Equation 12 is a special form of the Poisson differential equation which expresses the change of the electric field and the potential, respectively, around a single charge.

The effect of the electric field around a center-ion on the distribution of other ions in its surrounding and the decay of the electrical potential is illustrated in Fig. 2a, b which shows that the concentration of the excess charges around an ion

is decreasing exponentially with the distance from the center-ion.

The electrical potential surrounding a center-ion is also decreasing with the distance from the center-ion, and it will reach zero at a certain distance. This distance is called the Debye length and marks the outer boundary of the ion atmosphere.

The Electric Double Layer at the Surface Membranes

When membranes with fixed charges at the surface are immersed into an electrolyte solution

Basic Electrochemical Relations in Membrane Processes: Electron Conductivity, Ion Conductivity, Ohm's Law, and Coulomb's Law,

Fig. 3 Schematic drawing illustrating (a) the closest approach of hydrated cations to the negatively fixed ions of the surface of a cation-exchange membrane and (b) the potential dissipation in the double layer according to the Helmholtz model

charge, they will generate an electric field directed into an adjacent solution and attract, due to the Coulomb forces, ions with the opposite charge. This leads to a layer on the membrane surface in which the concentration of the oppositely charged ions is higher than in the bulk solution. In many aspects the fixed charges of the membrane behave very similar to the charges surrounding a single charge in an electrolyte solution. These ions will form a layer at a certain distance from the membrane surface, which neutralize the fixed charges at the membrane surface. This double layer at the interface between the ion-exchange membrane and the adjacent solution is kept in place by the attraction force of the electrical potential generated by the fixed ions of the membrane and the dispersing force of the thermal motion. This double layer at the interface between the membrane and the electrolyte solution, which is important for certain electrokinetic phenomena such as electro-osmosis or streaming potential, can be described by several models (Wagenen and Andrade 1980). The simplest one of these models is the Helmholtz model.

The Helmholtz Double Layer Model

Helmholtz postulates that all counterions necessary to neutralize the surface charge of an ion-exchange membrane are aligned in a single

layer in parallel at a certain distance from the membrane surface. This distance is determined by the radius of the hydrated counterion as indicated in Fig. 3.

The Helmholtz model resembles a parallel plate capacitor where the charge is determined by the number of charges at the surface and in a plane parallel to the membrane surface. The relation between the surface charges, the potential between the negatively and positively charged layers, and their distance are given by the same equation, which describes the capacitance of a parallel plate capacitor (Starzak 1984), i.e.,

$$C = \epsilon \frac{A}{4 \pi d} = \frac{q}{U} \quad (13)$$

Here C is the capacitance, A is the area of the charge surface, d is the thickness of the Helmholtz layer, and q is the charge.

Introducing the surface charge density σ which is given by

$$\sigma = \frac{q}{A} \quad (14)$$

and replacing the voltage U by the potential difference $\Delta\phi$ between the two layers

$$U = \Delta\phi \quad (15)$$

Basic Electrochemical Relations in Membrane Processes: Electron Conductivity, Ion Conductivity, Ohm's Law, and Coulomb's Law, Fig. 4 Schematic drawing illustrating (a) the excess counterions in the

double layer as function of the distance from the membrane surface and (b) the potential dissipation as function of the distance from the surface of the membrane

give a relation between the thickness of the double layer d , the surface charge, and the potential difference in the double layer:

$$\Delta \varphi = \frac{4\pi d}{\varepsilon} \sigma \quad (16)$$

Here ε is the permittivity and σ is the surface charge density.

The Gouy-Chapman Double Layer Model

The Helmholtz model contains a number of rather drastic simplifications. For example, it assumes that the fixed ions form a homogeneous sheet and that the counterions form a complementary parallel sheet not affected by the thermal motion of the solution. In reality this is not the case.

In the Gouy-Chapman model, the counterions in the solution are no longer assumed to be aligned in a sheet but will occupy a finite volume in a mixture of cat- and anions. The total number of counterions in this volume is identical to the fixed charges of the membrane surface. Their distribution, however, is such that the area close to the membrane surface contains the largest excess of counterions as indicated in Fig. 4 and is very similar to the ion atmosphere around a single charge.

In analogy to the potential decay around a single charge, the potential at a certain distance from the membrane surface carrying fixed charges

Basic Electrochemical Relations in Membrane Processes: Electron Conductivity, Ion Conductivity, Ohm's Law, and Coulomb's Law, Fig. 5 Schematic drawing illustrating the structure of a water molecule indicating the dipole character due to the uneven distribution of the electrical charges within the molecule

can be calculated by applying the Poisson equation which provides a relationship between the potential and the excess charges at a given point in the solution and under the assumption that the system obeys the Boltzmann statistic by

$$\Delta \varphi = \frac{\sigma x_D}{\varepsilon} \quad (17)$$

Here x_D is the Debye length which determines the thickness of the double layer. The Debye length is inversely proportional to the ion concentration of the solution. With increasing ion concentration, the Debye length is decreasing.

The boundary layer at the surface of membranes carrying fixed charges has a significant effect on the streaming potential and on the

Basic Electrochemical Relations in Membrane Processes: Electron Conductivity, Ion Conductivity, Ohm's Law, and Coulomb's Law, Fig. 6 Schematic drawing illustrating the distribution of water molecules (a) around a cation and (b) around an anion

B

electric osmotic water transport as well as on the so-called zeta potential (Lyklema 1995).

Electrical Dipoles and Intermolecular Forces

An electrical dipole consists of two opposite charges attached to a molecule and separated by a certain distance. An attraction of the charges is prevented by the rigidity of the molecular structure. The potential produced by the dipole is different from that produced by a single charge. The potential of a dipole with a single charge is decreasing with the distance by the square of the distance. The dipole momentum of molecules is measured in Debye [D] with $D = 3.33 \times 10^{-30} \text{ A s m}$. The dipole momentum varies substantially depending on the polarity of the molecules. It is 0 for a completely nonpolar molecule such as CCl_4 or H_2 and ca. 1.80 D for a polar molecule such as water (Atkins 1990). The high dipole momentum of the water is the result of the water molecule structure in which the hydrogen atoms are attached to one side of the oxygen atom as illustrated in Fig. 5.

The strong dipole momentum of water is also the reason for its good solubility properties for salts. The water dipoles tend to break the generally strong Coulomb forces between the negatively and positively charged ions of a salt crystal by surrounding the ions. Thus, in an aqueous solution, each ion is surrounded by a shell of water

molecules as indicated in Fig. 6(a) showing water molecules surrounding a cation and (b) water molecules surrounding an anion.

Another important result of the molecular interaction of water dipoles is the formation of the hydronium ions from protons and water. In water the proton recombines readily with the water molecule to the hydronium ion in which the three H atoms are no longer distinguishable and carry the positive charge together. The hydronium ion resembles a tripod with the three H atoms on one side and all equally apart from the oxygen atom. The rapid formation of the hydronium ion is the reason for the much faster transport of protons compared to other ions in an aqueous solution.

Batch Diafiltration

Zoltán Kovács

Department of Food Engineering, Institute of Bioengineering and Process Engineering, Szent Istvan University, Budapest, Hungary

Batch diafiltration refers to a pressure-driven membrane filtration process in which a diluant (pure solvent) is added into the feed tank in order to enhance the degree of separation of macrosolutes from microsolutes. In batch diafiltration, in contrast to continuous diafiltration, the retentate stream is recirculated to the feed tank, and only the permeate stream is collected separately. During the operation, solute-free diluant is introduced into the feed tank to replace solvent losses as schematically illustrated in Fig. 1. The requirement for an effective separation is the utilization of a membrane which highly retains the macrosolute but permeable for the microsolite. Thus, depending on the application, microfiltration, ultrafiltration, nanofiltration, or even reverse osmosis membranes can be applied.

In its strict, original sense, the term batch diafiltration refers to a process that aims at removing the microsolutes from the process liquor. The standard way of achieving this purification goal is to employ a constant-volume diafiltration (CVD) process that is probably the most common type of batch diafiltration. In CVD, the feed volume is kept constant by continuously adding a diluant at a rate equal to the permeation rate.

It should be pointed out that the removal of microsolutes and the concentration of macrosolutes (i.e., the reduction of the volume of process liquor) are both required for most applications. The term batch diafiltration, in its broader sense, may stand for a batch filtration process that is designed to achieve the twin objectives of concentrating and purifying a multi-solute system according to a specific diluant utilization strategy. In this context, batch diafiltration is a complex process that may involve a sequence of consecutive operational steps.

A straightforward way of achieving the dual objectives of concentration and fractionation is to combine CVD with concentration mode operational steps (i.e., in which no diluant is added into the feed tank). A so constructed typical three-step process, also referred to as traditional diafiltration (TD), involves the following phases: (i) concentration mode to achieve an intermediate macrosolute concentration, (ii) constant-volume diafiltration to “wash out” the microsolite by a pure solvent introduced into the system, and (iii) further concentration to the final desired macrosolute concentration. Beside TD, a number of alternative strategies have been proposed. These include the sequential dilution diafiltration (SDD), intermittent feed diafiltration (IFD), variable-volume diafiltration (VVD), pre-concentration combined with variable-volume diafiltration (CVVD), and dynamic-volume diafiltration (DVD).

Diafiltration techniques differ in controlling the addition of the diluant in terms of quantity and duration. The differences between the various

Batch Diafiltration,

Batch Diafiltration, Table 1 Diluant utilization strategies in batch diafiltration

Name	α - strategy
Constant-volume dilution	$\alpha = 1$
Traditional diafiltration	$\alpha = \{0, 1, 0\}$
Variable-volume diafiltration	$\alpha = \text{const}, 0 < \alpha < 1$
Preconcentration with variable-volume diafiltration	$\alpha = \{0, \alpha_1\}, \alpha_1 = \text{const}, 0 < \alpha_1 < 1$
Intermittent feed diafiltration	$\alpha = \{(0, \alpha_{\max})_n, 0\}$
Sequential dilution diafiltration	$\alpha = \{(\alpha_{\max}, 0)_n\}$
Dynamic-volume diafiltration	$\alpha = \alpha(t) \quad 0 \leq \alpha(t) \leq \alpha_{\max}$

n number of repetition

operations are best described by the proportionality factor α (i.e., the ratio of diluant flow $d(t)$ to permeate flow $q(t)$) as a function of operation time (Foley 2006). For instance, TD process is characterized with a sequence $\alpha(t) = \{0, 1, 0\}$ with two unknown switching times at the end of the first and of the second time interval. Similarly, CVVD process has two phases with constant α levels $\alpha(t) = \{0, \alpha_1\}$ and an unknown switching time. Table 1 shows the diluant control strategies applied in batch processing. Note that the best time-varying profile of diluant addition needs not necessarily be one of the arbitrarily predefined profiles. The diafiltration process, that is, designed by the evaluation of the optimal time-varying profile of the diluant flow, is referred to as dynamic-volume diafiltration (Paulen et al. 2012).

The governing differential equations for a generalized batch diafiltration process are given as

$$\frac{dc_i}{dt} = \frac{c_i q}{V} (R_i - \alpha), \quad c_i(0) = c_{i0}, \quad i = 1, 2$$

$$\frac{dV}{dt} = (\alpha - 1)q, \quad V(0) = V_0.$$

where c_i is the solute concentration in the feed tank, R_i the rejection of component i , and

V represents the feed tank volume. This initial value problem describes the evolution in time of the feed volume and the feed concentration of any solute under the assumption that the diluant is solute-free and the feed tank is well-mixed. Note that the time-dependent variables (i.e., permeate flux and the solute rejections) are, in a general case, a function of feed concentrations and may vary with operation conditions (temperature, pressure, cross-flow velocity, etc.).

The unique feature of realizing both concentration and fractionation puts membrane filtration in an attractive position and compares favorably with other separation methods or even with a sequence of consecutive unit operations. In comparison with continuous processes, batch operations are especially suited to small-scale operations, require less expensive automatic controls, and enable a reduced membrane area in order to reach the target (Baker 2004). Most batch plants operate under constant mechanistic membrane pressure adjusted simply by the retentate valve. There exist, however, other types of process control strategies in engineering practice, such as constant flux or constant wall concentration control (van Reis et al. 1997). These are normally employed when unfavorable side effects (e.g., enhanced fouling or product quality deterioration) occur that can be associated with the high concentration at the membrane wall.

Bed-to-Wall Mass Transfer Limitations

Alessio Caravella

National Institute of Advanced Industrial Science and Technology – Research Institute for Innovation in Sustainable Chemistry, ISC-AIST, Tsukuba, Ibaraki, Japan

Bed-to-wall mass transfer limitations. These phenomena, also referred to as “concentration polarization” in the field of *membrane technology* (Gallucci et al. 2011), are more generally related to the mass transfer resistance that a species encounters to reach an “active wall.” An “active wall” is a surface where physical and/or chemical transformations (including adsorption/desorption phenomenon and solubilization/desolubilization processes) occur.

The main cases of interest in chemical engineering are reported in Fig. 1. As for the former (Fig. 1a), an impermeable catalytic wall is considered, where the reactant species A reaches the catalytic surface and is transformed, as an

instance, into the product B, this being representative of all possible reactions. If the reaction rate is sufficiently fast, the transport through the gas phase becomes limiting and, thus, a significant concentration/pressure drop is generated, decreasing in fact the effective concentration of species A that can be involved in the surface reaction with respect to the bulk concentration.

As for the second case (*concentration polarization*, Fig. 1b), a membrane permeable to both species A and B is considered, with the species A being the one to separate and more permeable (higher transmembrane flux) than the species B. Because of the effect of the higher flux of the species A, the species B is “pushed” toward the membrane wall, generating in this way an obstacle for the species A to reach the surface. *Concentration polarization* is not desired for two main reasons. First, it causes a decrease in the permeation driving force of the species A, as the surface-surface concentration difference is smaller than the bulk-bulk one. Second, it tends to favor the permeation of the less-permeating species (B), causing the actual membrane *separation factor* to decrease.

Bed-to-Wall Mass Transfer Limitations, Fig. 1 Schematic representations of the two most common cases of bed-to-wall mass transfer limitations. (a) Case of impermeable catalytic wall on which a chemical

reaction takes place and (b) Case of membrane (permeable wall) through which all the components can, in general, pass. Membrane is supposed to be impermeable to the species C

Beer Clarification

Frank Lipnizki
Alfa Laval Copenhagen, Søborg, Copenhagen,
Denmark

In the traditional brewing process, the beer is clarified after fermentation and before maturation to remove mainly the remaining yeast but also microorganisms and haze. The conventional process for beer clarification is the combination of a high-speed separator followed by diatomaceous earth (DE)/kieselguhr filtration which is complemented in some cases by second filtration with PVP (polyvinylpyrrolidone) to obtain a very clear beer. The major challenge of the conventional process is related to the DE filtration because the DE can vary in quality and is problematic for handling and disposal since it is hazardous plus DE filtration generates large amounts of effluent. Alternatively, from its introduction in 2001 (Buttrick 2007) cross-flow microfiltration has established itself in the brewing industry with over 50 breweries worldwide adopting this DE-free beer filtration. Generally, three concepts are currently used in the industry:

1. Beer Membrane Filtration (BMF) by Pentair (previously Norit) – a system based on hollow fiber microfiltration cartridges without a high-speed separator as pretreatment
2. PROFi Membrane System by Pall and GEA Westfalia – a combination of hollow fiber microfiltration system with a high-speed separator as pretreatment

Beer Clarification, Table 1 Comparison of key parameters of beer filtered with DE filtration and microfiltration (Lipnizki 2005)

	Beer before filtration	Beer after DE filtration	Beer after microfiltration
Original extract [%]	11.40	11.37	11.39
Alcohol [%]	3.84	3.83	3.84
Color [EBC]	7.20	6.70	7.00
Viscosity [MPas]	1.62	1.57	1.56
Turbidity at 0 °C [EBC]	32.00	0.53	0.41

3. AlfaBright system by Alfa Laval and Sartorius – a process based on the combination of cassette microfiltration system with a high-speed separator as pretreatment

The membranes established for beer filtration are all polymeric microfiltration membranes based on polyethersulfone with 0.5–0.65 μm pores and beer capacities of 0.5–1.0 $\text{hl}/(\text{m}^2 \text{ h})$ (Buttrick 2007). The resulting beer quality from the membranes is similar or improved compared to the DE filtration; in Table 1 a comparison between beer filtered by DE and microfiltration membranes is given. Other membranes, e.g., ceramic membranes, have been tested for beer filtration but so far have not established themselves on the market. The key difference between the three concepts is the use of a high-speed separator as pretreatment. In the BMF system a retentate tank is used to collect the beer solids, while both the PROFi and the AlfaBright systems are using high-speed separators as pretreatment before the membrane to remove the beer solids and thus eliminating the need for a retentate tank. The systems can be typically run in batch or continuous operation depending on the size and requirements of the individual brewery. In batch operation, the complete system shifts from filtration into cleaning mode after each batch. Plants with continuous operation are arranged in

skids/blocks and use sequential cleaning which allows for some skids/blocks to be in standby cleaning mode, while other blocks are in filtration mode. The major challenges for cross-flow membrane beer filtration are the relatively high investment costs and complexity of the process when compared to DE filtration and the increasing availability of alternative DE-free filter aids.

Beer Dealcoholization

Frank Lipnizki
Alfa Laval Copenhagen, Søborg, Copenhagen,
Denmark

In the last decades the demand for low alcohol and alcohol-free drinks increased, e.g., in Germany the annual consumption of alcohol-free drinks nearly doubled from 130.4 l per person in 1980 to 248.2 l person in 1999, while the annual consumption of alcoholic drinks declined from 179.5 to 156.3 l during the same period (Gebhardt 2001). Conventionally beer can be dealcoholized by distillation, but additionally the membrane process reverse osmosis and dialysis have established themselves for the partial dealcoholization of beer by eight to ten times. The key advantage of membrane processes over distillation is that beer can be dealcoholized at low temperatures typically 78 °C to minimize the effect of temperature on the beer flavor resulting in high-quality low alcohol beer, which can be bottled after final sterile filtration.

Reverse osmosis is typically carried out in spiral wound modules, and the dealcoholization

process based on reverse osmosis can be divided into four individual operations which are typically carried out in batch mode:

1. **Pre-concentration:** In this step the volume of the feed beer is reduced. The beer is passed through the membrane modules and is then recycled to the batch tank. The permeate – water and alcohol – is removed from the process, while retentate, concentrated beer and flavors, is returned to the batch tank.
2. **Diafiltration:** This step is similar to the pre-concentration step but diafiltration water – desalted and deoxygenized water – is added to wash out the alcohol. The amount of diafiltration water added balances the amount of permeate removed from the process, and thus, the level in the batch tank remains constant. This operation is continued until the desired alcohol concentrations in the beer are achieved.
3. **Alcohol adjustment:** In this step, the taste and alcohol content is fine-tuned by addition of desalted and deoxygenized water.
4. **Posttreatment:** In order to give the beer its specific character and to balance taste losses due to removal of the taste carrier alcohol, the CO₂ levels can be adjusted, and hop extract, syrup, or other flavor enhancers are added.

As an alternative to reverse osmosis, dialysis can be used for the dealcoholization of beer. Commonly, hollow fiber modules are used for dialysis allowing the beer to flow on one side of the membrane and water as dialysate on the other side. The process is normally operated in counter-current flow to maximize the concentration gradient over the dialysis membrane and thus the driving force of the dialysis process. The dialysate is constantly recycled over a steam stripping column to remove the alcohols, thus maintaining the driving force of the process while minimizing the dialysate consumption. In addition, in order to minimize CO₂ losses, the feed pressure should be selected close to the CO₂ saturation pressure, and small amounts of the CO₂ should be added to the dialysate (Branyik et al. 2012).

Furthermore, osmotic distillation for beer dealcoholization (Russo et al. 2013) and pervaporation for aroma recovery can be considered as part of the beer dealcoholization process (del Olmo et al. 2012), but so far these processes are not commercialized.

Beer Maturation

Frank Lipnizki
Alfa Laval Copenhagen, Søborg, Copenhagen,
Denmark

In the beer production process, the clarified and cooled wort from the brewhouse is transferred together with yeast to the fermentation tanks for the primary fermentation which converts the fermentable sugar into alcohol and CO₂. The resulting “green beer” undergoes a second fermentation – beer maturation – under addition of sugar or fresh yeasted wort. During the maturation, the residual fermentable sugars in the “green beer” will be converted to alcohol and the beer will be saturated with CO₂. After the fermentation, the beer is clarified and stored in the bright beer cellar. Remaining in the fermentation tanks are tank bottoms – a mixture of settled yeast cells and beer – which are equal approx. 1.5–2.0 % of

the fermentation tank volume. In the past this beer in the tank bottom would be considered lost since it could not be added to the main beer stream. However, using microfiltration with tubular ceramic membranes or plate-and-frame modules with polymeric membranes, it is possible to recover a high-quality beer which can be blended with the main beer stream going toward clarification and storage. Using microfiltration membranes with pores of 0.4–0.5 µm, it is possible to retain the yeast and allow the beer to pass the membrane without any major impact on the quality of the beer. In this process, the yeast in the tank bottoms is concentrated from 7 % to 10 % DM to approx. 20 % DM and thus 50–70 % of the beer in the tank bottoms can be recovered. The yield of recovered extract and alcohols can be further maximized if diafiltration water is added. Recovering beer from tank bottoms can increase the output of an average brewery by 1 % of its annual production or 24,000 hl extra for a brewery with an annual output of 2 million hl (Lipnizki 2005). The amortization for a microfiltration beer recovery unit is typically 1–2 years.

Benzene and Cyclohexane Separation

Tadashi Uragami
Organization for Research and Development of Innovative Science and Technology (ORDIST),
Kansai University, Suita, Osaka, Japan

Benzene/Cyclohexane Separation

In the petrochemical industry, the separation of benzene (Bz) and cyclohexane (Chx) is the most

Benzene and Cyclohexane Separation, Fig. 1 Principle of pervaporation (PV)

important and difficult processes. Chx is produced in benzene hydrogenation units under Ni or Pd catalyst. The unreacted Bz is remained in the reaction mixture and must be removed to produce pure Chx. The separation of benzene and Chx is very difficult by a conventional distillation because close-boiling point mixtures are formed in the entire range of their compositions. At present, azeotropic distillation and extractive distillation are applied to this separation. These distillations, however, are complex and need high energy consumption. In the industry of Chx production, the conventional Bz/Chx separation processes are strongly required. Therefore, many studies have investigated the PV properties of polymer membranes for Bz/Chx separation.

Pervaporation (PV) is a promising membrane technique for the separation of organic/organic mixtures, as PV can be used to separate organic liquid mixtures such as azeotropic and close-boiling point mixtures. The separation mechanism in PV is not based on only relative volatility of components in distillation but on the difference in sorption and diffusion properties of the feed substances.

Figure 1 illustrates the principles of PV. In this separation process, when a liquid mixture is fed to the upstream side of a polymer membrane and the downstream side is evacuated, a component in the

feed mixture can preferentially permeate through the membrane. In a PV process, differences between the solubility and diffusivity of the mixture components in the polymer membrane and the relative volatility of the permeants determine the permeability and selectivity (Binding et al. 1961; Aptel et al. 1974). In general, PV exhibits the following characteristics (Uragami 2006, 2010):

1. Selective transport across the nonporous membrane is achieved by a three-step process of solution, diffusion, and evaporation.
2. Because the driving force for permeation is the vapor pressure for each component rather than total system pressure, this method is effective for separation of organic liquid mixtures with high osmotic pressure.
3. PV can be applied to the separation and concentration of mixtures that are difficult to separate by distillation. For example, it is useful for the separations of azeotropic mixtures, close-boiling point mixtures, and structural isomers.
4. PV can be used for the removal of certain components in equilibrium reactions.
5. Polymer membrane compaction, a frequent problem in high-pressure gas separations, is not encountered in PV because the feed pressure is typically low.

A side-chain liquid-crystalline polymer (LCP) was synthesized by the addition of mesogenic monomer to poly(methylsiloxane) with a Pt catalyst. When Bz/Chx mixtures were permeated through the LCP membranes by PV at various temperatures, the permeation rate increased with increasing benzene concentration in the feed solution and permeation temperature. Although the LCP membranes exhibited Bz/Chx selectivity, the mechanism responsible for the permeation and separation of the Bz/Chx mixtures was different in the glassy, liquid-crystalline state versus the isotropic state of the LCP membranes. These results suggest that the Bz/Chx selectivity was

moderately influenced by the change in LCP membrane structure (i.e., a state transformation). The balance between the orientation of the mesogenic groups and the flexibility of the siloxane chain is very important with respect to permeability and Bz/Chx selectivity (Inui et al. 1997, 1998). When benzene/cyclohexane, toluene/cyclohexane, and *o*-xylene/cyclohexane mixtures were subjected to PV through an LCP membrane in the liquid-crystalline state, the permeation rate increased with increasing temperature and the LCP membrane exhibited selectivity for the aromatic hydrocarbons. The permeation rate and selectivity of the LCP membrane for each mixture decreased with increasing molecular size of the aromatic hydrocarbon in the binary feed mixture (Inui et al. 1998). When Bz/Chx mixtures were permeated through nematic and smectic side-chain liquid-crystalline polymer (*n*- and *s*-LCP) membranes under various conditions during PV, the *n*- and *s*-LCP membranes exhibited Bz/Chx selectivity. The selectivity of the *n*-LCP membrane changed from solubility-selectivity controlled to diffusion-selectivity controlled upon the state transformation of the membrane, induced by an increase in the permeation temperature. In contrast, the selectivity of the *s*-LCP membrane was governed by diffusion selectivity regardless of the state of this membrane. At low permeation temperatures, the *n*-LCP membrane in the liquid-crystalline state exhibited lower permeability but higher selectivity than the *s*-LCP membrane. However, at high permeation temperatures, the relationship between the permeability and Bz/Chx selectivity of the *n*-LCP and *s*-LCP membranes in the liquid-crystalline state was reversed. These results are a result of differences in the chemical and physical structure of the *n*-LCP and *s*-LCP membranes (Inui et al. 1998).

The PV properties of a series of cross-linked 4,4'-hexafluoro-isopropylidene dianhydride (6FDA)-based copolyimide membranes for the separation of Bz/Chx mixtures were investigated (Ren et al. 2001). The glassy, highly rigid copolyimides were obtained by polycondensation

of 6FDA with various diamines. To obtain high permeability as well as high selectivity, a combination of the diamines 2,3,5,6-tetramethyl-1,4-phenylene diamine (4MPD), 4,4'-hexafluoroisopropylidene dianiline (6FpDA), and 3,5-diaminobenzoic acid (DABA) as monomers with a crosslinkable group was used. Cross-linking is necessary to prevent undesirable swelling effects, which generally occur with non-cross-linked polyimides, especially if high benzene concentrations are reached during PV. The degree of cross-linking was kept constant at 20 %, whereas the ratio of the diamine monomers 6FpDA and 4MPD was varied. The PV experiments were performed at 60 °C, using Bz/Chx mixtures with benzene concentrations covering the entire concentration range. All of the cross-linked polymers had excellent chemical and thermal stability in the PV experiments. In all cases, conditioning of the membrane samples with pure benzene was a suitable pretreatment to enhance the permeation rate without decreasing the Bz/Chx selectivity significantly. For the most promising membrane material, 6FDA-4MPD/DABA of 4:1 cross-linked with ethylene glycol, the PV experiments were performed with a benzene/cyclohexane feed mixture of 50/50 (w/w) over a temperature range between 60 °C and 110 °C to determine the effect of temperature on the separation characteristics.

Benzyl-Modified Cellulose

Hongyang Ma, Benjamin S. Hsiao and Benjamin Chu
Department of Chemistry, Stony Brook University, Stony Brook, NY, USA

Benzyl-modified cellulose contains covalently bonded benzyl groups in the cellulose structure, typically produced by etherification of hydroxyl groups (Bowry and Rintelen 1998) shown in Fig. 1.

Benzyl-Modified Cellulose,

Fig. 1 Synthetically modified cellulose from benzyl-modified cellulose by etherification

The benzylation of cellulose can lead to several useful applications. For example, in blood hemodialysis, membrane filtration is a key process for the replacement of renal function in uremic patients. The hydroxyl groups in cellulose can activate complement function, which is an undesirable process in hemodialysis. A certain amount of the substitution of hydroxyl groups with benzyl groups, being known as synthetically modified cellulose (SMC), can help minimize the complement activation, by balancing the hydrophilic and hydrophobic domains in the cellulose structure (Hoenich et al. 1997).

Another application of benzylation of cellulose is the fabrication of natural fiber composites by the surface modification of cellulose through the route shown in Fig. 1 (Lu et al. 2004). The fiber composites exhibit excellent thermal formability and mechanical properties, enabled by the benzyl cellulose skin layer and natural cellulose core (Zhang et al. 2005).

It should be noted that the benzylation of cellulose, as mentioned above, can produce a heterogeneous structure with only the skin of the cellulose structure being modified. A homogeneous benzylation of cellulose has been achieved when ionic liquids were used as the solvent for cellulose (Gericke et al. 2012). *N*-alkylpyridinium chlorides can be used to dissolve cellulose and then react with benzyl groups, resulting in benzyl cellulose with a high degree of substitution. It is possible that the surface modification of fibrous mats with benzyl cellulose can be achieved by surface coating and thereby forming a non-covalently bonded modification approach (Ma et al. 2014).

Bilberry Aroma Recovery by Pervaporation

Immaculada Ortiz and Nazely Diban
Department of Chemical and Biomolecular
Engineering, University of Cantabria, Santander,
Cantabria, Spain

Introduction

Pervaporation (PV) is a membrane-based technology largely studied for aroma compound recovery and concentration in the food industry (Pereira et al. 2006). At least two PV pilot plants for aroma compound recovery have been built at Membrane Technology and Research (MTR)

Inc., California (EEUU), and Agrotechnology & Food Innovations (A&F) in the Netherlands (Willemsen et al. 2004), and theoretical studies assessing the recovery and concentration of aroma compounds by means of PV have demonstrated the viability of this technology at industrial scale (Karlsson et al. 1998; Lipnizki et al. 2002a, b; Trifunovic et al. 2006). During the PV, the aroma compounds contained in a liquid or feed phase permeate selectively through a dense hydrophobic membrane due to the chemical potential gradient caused by a reduction of the component partial pressure in the permeate side. The aroma compounds are preferentially transported through the membrane according to their affinity to the membrane material and their mobility in the membrane matrix, which is the hypothesis of the most accepted mass transport mechanism in PV known as solution-diffusion.

Bilberry (*Vaccinium myrtillus* L.) is a species of shrub and is native from Europe, northwest regions of North America, and Northern Asia (Morton and Macleod 1990). The international markets' demand of bilberry's extract has been steadily growing in the recent years (Foster and Blumenthal 2012). The major aroma compounds present in crushed bilberry were identified by gas chromatography-mass spectroscopy (GC-MS). The results are shown in Fig. 1. Trans-Hex-2-en-1-ol was characterized as one of the impact flavor of the bilberry (von Sydow and Anjou 1969).

Membrane Material and Module Configurations

The most typical organophilic membrane materials employed in PV of aroma compounds in the literature are polydimethylsiloxane (PDMS) and polyoctylmethylsiloxane (POMS). POMS membranes present higher enrichment factors for aroma compounds than PDMS albeit not significantly different. Nonetheless, PDMS membranes are largely more studied due to their stability during operation and good properties of processing (Karlsson and Trägårdh 1993; Lipnizki et al. 1999; Uriaga et al. 1999).

Bilberry Aroma Recovery by Pervaporation, Fig. 1 GC-MS chromatogram of the crushed bilberry: (1) trans-hexenal, (2) 2-butyl-1-octanol, (3) 1-hexanol,

(4) trans-Hex-2-en-1-ol, and (5) 1-hexadecanol (Adapted from (Garcia et al. 2008))

With regard to the membrane module configurations, plate-and-frame is the most employed in literature for laboratory scale studies for their simplicity and versatility for the evaluation of different membrane materials. However, the hollow fibers membrane (HFM) module configuration presents important advantages, such as higher contact area per unit volume of membrane module and thus higher compactness of the equipment and easier operation at industrial scale (Urtiaga et al. 1999, 2002; Tasselli et al. 2007).

Influence of Process Variables

Using a model ternary solution (water/ethanol/trans-Hex-2-en-1-ol), the process variables that exerted an important influence on the PV performance of the impact aroma compound (trans-Hex-2-en-1-ol) when using a PDMS HFM module with the characteristics presented at (Garcia et al. 2008) were:

- (i) The feed composition (ethanol and aroma compound). The results are presented in Fig. 2. As expected, ethanol flux, J_{EtOH} , increased linearly with higher ethanol content in the feed, while in contrast, aroma compound partial flux, J_{Hex} , remained independent on ethanol concentration but presented a linear dependency with its own concentration in the feed solution. The major component flux, water, was independent on both ethanol and aroma compound composition. The enrichment factors found for the aroma compound, β_{Hex} , varied from 98 to 201.
- (ii) The feed temperature, studied in the range $35\text{ }^{\circ}\text{C} < T < 50\text{ }^{\circ}\text{C}$. The components' partial fluxes (water, ethanol, and trans-Hex-2-en-1-ol) were found to follow an Arrhenius dependency with temperature as plotted in Fig. 3.

Bilberry Aroma Recovery by Pervaporation, Fig. 2 (a) Effect of ethanol concentration in the feed on the permeation flux of the ethanol in (■) binary water/ethanol and (◇) ternary water/ethanol/Hex mixtures, and (▲) flux of trans-hex-2-en-1-ol in ternary mixtures

[Hex] = 0.1 kg.m⁻³, $T = 50^\circ\text{C}$ and $Re = 772$. (b) Effect of trans-hex-2-en-1-ol partial pressure in the feed on its permeation flux at 50°C , $Re = 772$, and [EtOH] = 1%v/v (Adapted from (Garcia et al. 2008))

Bilberry Aroma Recovery by Pervaporation, Fig. 3 Effect of the feed temperature on the partial fluxes of the components when $Re = 772$, [Hex] = 0.1 kg.m⁻³, and [EtOH] = 1%v/v (Adapted from (Garcia et al. 2008))

In the present application and working under laminar flow rate conditions, $203 < Re < 772$, the aroma compound transfer flux was independent on the feed flow rate. This indicated that the concentration polarization phenomena in the feed boundary layer was negligible in comparison with the aroma compound mass transfer resistance in the membrane which normally occurs with high membrane thickness, i.e., 127 and 160 μm (Peng and Liu 2003;

Kanani et al. 2003), similar to the membrane thickness herein studied, 196 μm .

PV of Multicomponent Systems

PV of multicomponent systems of the bilberry characteristic aroma flavor was performed theoretically by means of simulation considering the composition in Table 1 and commercial PDMS HFM modules. The membrane area considered was $A_m = 0.0056 \text{ m}^2$ and the membrane

Bilberry Aroma Recovery by Pervaporation, Table 1 Feed composition (found in Hirvi and Honkanen 1983), and simulation results of the permeate composition, enrichment factors, and partial fluxes in the bilberry multicomponent system after PV with a PDMS HFM module at 30 °C and a membrane area $A_m = 0.0056 \text{ m}^2$ (Diban et al. 2008)

Component	Feed composition, C_i^F (mg.kg ⁻¹)	Permeate composition, C_i^P (mg.kg ⁻¹)	β_i	J_i (g.m ⁻² .h ⁻¹)
Trans-Hex-2-en-1-ol	0.01	1.21	120.6	3.78×10^{-5}
n-Hexanol	0.02	4.74	236.9	14.9×10^{-5}
Trans-Hex-2-en-1-al	0.06	2.78	46.3	8.70×10^{-5}
Linalool	0.004	0.20	49.3	0.62×10^{-5}
Phenyl acetaldehyde	0.003	0.02	5.5	0.05×10^{-5}

Bilberry Aroma Recovery by Pervaporation, Fig. 4 Change of the partial flux of trans-Hex-2-en-1-ol, J_{Hex} , and enrichment factor, β_{Hex} , with the membrane

thickness, δ . $T = 30 \text{ }^\circ\text{C}$, $[\text{Hex}] = 10^{-5} \text{ kg.m}^{-3}$, $[\text{EtOH}] = 1\% \text{ v/v}$, $Re \sim 6 \times 10^5$, $A_m = 0.0056 \text{ m}^2$ (Adapted from Diban et al. 2008)

thickness, δ , was $1.96 \times 10^{-4} \text{ m}$. Further details of the simulation conditions can be found in (Diban et al. 2008). The results of the simulation are collected in Table 1. There is a clear change in the component profile from the feed solution to the permeate aroma compound concentrate.

Moreover, the theoretical evaluation of the influence of the membrane thickness, δ , on the performance of the PV of trans-Hex-2-en-1-ol was performed. The results are plotted in Fig. 4. From these results, it is extracted that a commercially available membrane with a thickness of $1.48 \times 10^{-4} \text{ m}$ led to a compromise situation with important impact aroma compound enrichment factors $\beta_{Hex} \sim 90$ and adequate fluxes $J_{Hex} \sim 3 \times 10^{-5} \text{ g.m}^{-2}.\text{h}^{-1}$.

Future Directions

1. Experimental assessment of the behavior of real solutions to evaluate (i) the interaction between different molecules during PV and (ii) the aroma profiles in the permeate.
2. Integration of a sensory evaluation of the quality of the aroma compound concentrate that, independently of the aroma profile, is mainly affected by the presence of the impact aroma compounds in the permeate.
3. Evaluation of other membrane materials that reduce water mass transfer and enhance the aroma compound enrichment factors with the minimum flux reduction, such as POMS.

Bimetallic Electrocatalyst for Fuel Cells

Dmitri Bessarabov

Faculty of Engineering, DST HySA Infrastructure Center of Competence, North-West University, Potchefstroom, South Africa

General Requirements for Fuel Cells

Most of the known today fuel cell systems (e.g., automotive, portable applications, backup power, etc.) have common requirements that include reduction in costs, improvement in performance and durability, increase in tolerance toward impurities in the feed fuel, etc. (Vielstich et al. 2003a; Debe 2012).

Pt-based Electrocatalyst: Key Component

The platinum-based electrocatalyst used in PEM (proton-exchange membrane, also called polymer electrolyte membrane) fuel cells, PAFC (phosphoric acid fuel cell), and DMFC (direct methanol fuel cell) is one of the key components and directly influences performance, durability, costs, etc. More specifically, in the PEM fuel cell, the oxygen reduction reaction (ORR) occurring at the cathode is known to have slow kinetics, leading to large cathodic overpotential losses under typical operating conditions. In the case of specific application of PEM fuel cells, when hydrogen is produced from a reformat, an additional requirement such as tolerance of the anode electrocatalyst toward the traces of CO in the feed fuel stream must also be met. In order to reduce

costs of the fuel cells, an increased mass activity of the cathode electrocatalyst is required that would allow a decrease in the amount of the electrocatalyst in a fuel cell device.

Advanced Electrocatalysts

A search for better ORR electrocatalysts for PEM fuel cells that meet advance requirements has resulted in the development of various Pt-based bimetallic compounds (these can include alloys or intermetallic systems). It is believed that the improved performance (i.e., activity enhancement) of bimetallic alloys as electrocatalysts could be explained by the structural modification of Pt 5d orbital, coordination number of Pt, and modification in adsorption of oxygenated species from the electrolyte to the Pt or the alloying metal. For example, alloying results in a lattice contraction, leading to a more favorable Pt-Pt distance for the dissociative adsorption of oxygen (Vielstich et al. 2003b; Zhang 2008).

Pt+Cr, Pt+Ni, and Pt+Co bimetallic electrocatalysts have been demonstrated to show two- to threefold increase in their activities for ORR. The activation energy for oxygen reduction was also shown to be lower than that in Pt. However, it is also well recognized that these bimetallic electrocatalysts are subject to significant degradation rates (sintering/dissolution) as well as carbon-support corrosion under specific voltage cycling conditions that are common for automotive drive cycles during fuel cell startup and shutdown.

A lot of efforts have also been made during the last two decades to improve anode electrocatalyst in fuel cells that are designed to use hydrogen obtained by means of reforming other fuels. In that case an anode electrocatalyst is required for hydrogen oxidation reaction to take place in the presence of CO, as well as to improve performance of the methanol fuel cells. The focus has been on the development of bimetallic platinum-based electrocatalysts to reduce the amount of adsorbed CO and/or to improve performance of

electrooxidation of CO. Many metals have been considered for modifying the activity of the platinum catalyst, but only a few of them (Ru, Ir, Sn, Mo, etc.) lead to improved performances. The most studied bimetallic electrocatalyst is the family of Pt/Ru alloys, which enhance greatly the rate of oxidation of many alcohols (methanol, ethanol, etc.).

Current Trends

Research and development in the area of bimetallic and ternary electrocatalysts is ongoing. The trend is to make use of unique nanoscale structural effects that can be observed in structurally modified alloys (e.g., de-alloyed Pt-based catalysts) and intermetallic systems to enhance greatly ORR. These include novel structures observed in thin film extended surfaces (Stamenkovic et al. 2007; Debe 2012) as well as a multilayer Pt-skin surface (Wang et al. 2011, 2012).

Bioactive Compounds

Carmela Conidi

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

“Bioactive compounds” are extranutritional constituents that typically occur in small quantities in foods and can be shown to have an effect on human health.

Bioactive compounds are also referred as *nutraceuticals*, a term that reflects their existence in the human diet and their biological activity.

They consist of a wide range of chemical compounds with different structures, physiological activities, and molecular mass between 200 and 1000 Da (Pennington 2002).

Typical bioactive compounds include:

- Carotenoids (α -carotene, β -carotene, lycopene, lutein)
- Flavonoids (flavanols/flavans, isoflavones/isoflavonoids, flavanones, flavones, anthocyanins)
- Phenolic acids (cinnamic acid, caffeic acid, chlorogenic acid, p-coumaric acid, ferulic acid, citric acid, ellagic acid, vanillic acid, hydroxytyrosol, tyrosol, oleuropein)
- Plant sterols (beta-sitosterol, campesterol, phytosterol, saponin, squalene, stigmasterol, stanol)
- Resveratrol
- Probiotics
- Omega-3 fatty acids (α -linoleic acid)
- Proteins
- Organosulfur compounds (allyl/diallyl sulfides)
- Indoles
- Monoterpenes (limonene, perillyl alcohol)

Bioactive compounds have been intensively studied in order to evaluate their effects on human health, and numerous methodological approaches have been implemented to clarify their biological effect and mechanism of action.

For example, phenolic compounds and flavonoids from vegetable sources such as cereals, legumes, olives, and fruits exhibit antioxidant, anti-inflammatory properties, and different studies have reported protective associations between flavonoids and cardiovascular disease (CVD) and cancer.

Hydroxytyrosol, one of the most important phenolic compounds in olives, olive oil, and olive mill wastewaters, presents a strong antioxidant and anticancer properties.

Resveratrol, found in red wine, has antioxidant, antithrombotic, and anti-inflammatory properties and inhibits carcinogenesis. Lycopene, a potent antioxidant carotenoid in tomatoes and fruits, presents a protection against prostate and other cancers and inhibits tumor cell growth in animals.

Organosulfur compounds in onions and monoterpenes in citrus fruits have shown anticarcinogenic actions in experimental models, as well as cardioprotective effects.

Bioactive compounds are the main source of new drugs, functional food, and food additives. In fact, more than 80 % of food active compounds and more than 30 % of drugs are produced from bioactive natural products and the annual growth rate of natural drugs is 20 %.

As a result, the research of appropriate techniques for the separation of these compounds from complex matrix has attracted much attention in the last years. Generally, the separation of target compounds includes extraction and purification steps.

Several techniques have been proposed for the separation of bioactive compounds including solvent extraction, irradiation-assisted extraction, ultrasound-assisted extraction, heat treatment, enzyme-assisted extraction, supercritical fluid extraction, resin-based extraction, and chromatography purification techniques (Azmir et al. 2013).

These separation methods are characterized by some drawbacks, such as the degradation of the compounds of interest due to high temperatures and long extraction times (as in solvent

Bioactive Compounds, Table 1 Typical membrane operations for the separation of bioactive compounds from different sources

Bioactive compounds	Examples	Sources	Membrane processes
<i>Flavonoids</i>	Quercetin, catechin	Apple juice, tea, red wine	MF, UF, NF, RO
	Narirutin, naringin, hesperidin, neohesperidin	Citrus juices	MF, UF, NF, RO
	Apigenin, luteolin	Artichoke wastewaters	UF, NF, RO
	Cyanidin, cyanin, myrtillin	Red orange and pomegranate juices	MF, UF, NF, RO
<i>Carotenoids</i>	α -Carotene, β -carotene	Palm oil, carrot juice	MF, NF
	Lycopene, lutein	Carrot, kiwifruit, and tomato juices	MF, UF
<i>Phenolic acids</i>	Caffeic acid, chlorogenic acid, p-coumaric acid, ferulic acid	Apple juice, olive mill, and artichoke wastewaters	MF, UF, NF, RO
	Citric acid	Citrus juices	MF, UF, NF, RO
	Ellagic acid	Blackberry juices	UF, NF
	Tyrosol, hydroxytyrosol oleuropein, gallic acid	Olive mill wastewaters	MF, UF, NF, RO
<i>Proteins</i>	α -Lactalbumin, β -lactalbumin, bovine serum albumin (BSA)	Whey, milk	MF, UF, NF
	Immunoglobulines	Egg yolk	UF
	Phycocyanin	Marine organisms (microalgae)	UF, NF, RO
<i>Omega-3 fatty acids</i>	Linoleic acid	Fish-processing wastes	MF, UF, NF

extractions) and health-related risks. In addition, they involve high capital costs.

Recently, membrane technology has attracted attention as an alternative molecular separation technology due to its advantages such as high efficiency, simple equipment, easy scale-up, and low energy consumption. In general, membrane separations can operate under mild conditions of temperature, pressure, and shear stress, therefore preserving the biological activity of the compounds to be recovered and the properties of the original product; they do not require any extraction mass agents such as solvents, avoiding product contaminations and the need for subsequent purification.

Particularly, pressure-driven membrane technologies such as microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO) are extremely efficient for the separation, fractionation, purification, and

concentration of different classes of bioactive compounds from a complex mixture and in the recovery of intermediate compounds (Cassano and Drioli 2014).

Membrane operations in sequential design are particularly suitable alternative for recovery/concentration of bioactive phenolic compounds from fruit juices and food-producing wastewaters. MF and UF are typically applied for preliminary treatment while the purification and concentration steps are usually performed by NF and RO membranes.

The separation of bioactive proteins from milk and marine sources with UF and NF membranes results in high selectivity due to the large molecular weight differences between the target compounds.

Typical examples of membrane operations used for the separation of bioactive compounds are summarized in Table 1.

Bioadhesion to Membrane Surface

Li-Ping Zhu

MOE Key Laboratory of Macromolecular Synthesis and Functionalization, Department of Polymer Science and Engineering, Zhejiang University, Hangzhou, Zhejiang, China

Bioadhesion to membrane surface refers to the special interaction between biological organisms to membrane surfaces. The term “bioadhesion” generally describes the adherence of materials (natural or synthetic) to biological surfaces or the firm attachment of biological substances (such as microorganisms, proteins, cells, biomolecules, etc.) on material surfaces (Huang et al. 1999). As an interface phenomenon, bioadhesion is similar to conventional adhesion, except for the special characteristics of biological organisms and surfaces. As such, this term covers the adhesive properties of both synthetic components and the natural surfaces (such as cells) (Jacek et al. 1999). Bioadhesion also includes the use of bioadhesive (natural polymeric materials, such as proteins and carbohydrates) to stick two surfaces together (Palacio and Bhushan 2012). In medicine and biology, sometimes bioadhesion is also used as a synonym of mucoadhesion, which refers to the process whereby synthetic and natural macromolecules adhere to mucosal surfaces in the body

(Woodley 2001). Bioadhesion to membrane surface is often related with biofouling of membrane surface and thus receives much attention in membrane technology, particularly in biomedical membrane separation.

In blood-contact membrane separation, for the blood-incompatible membrane materials, the platelets in the blood tend to accumulate and adhere onto membrane surface due to a biological immune reaction. As a result, thrombus formation may form and further result in some serious complications. Therefore, the blood-contact membranes such as hemodialysis membranes often need be modified to prevent the adhesion of platelets on membrane surface during blood filtration. In membrane science, the experiment of platelet adhesion on membrane surface is usually employed to evaluate the hemocompatibility of a blood-contact membrane. In biomedical application, the adhesion of microbes on membrane surface often leads to the bacterial infection of patients and the deterioration of membrane materials. Therefore, the control of microbial infection is a very important issue in biomedical membrane separation.

Artificial liver; BAL; Biohybrid Artificial Liver (BAL)

Bioartificial Liver

Bioartificial liver is a system that consists of functional liver cells (hepatocytes) supported by an artificial cell culture environment. In particular it incorporates hepatocytes into a bioreactor, or biochemical reactor, in which cells are embedded and/or immobilized, cultured, and induced to perform all the liver-specific functions of the *in vivo* native liver: detoxification, biotransformation, excretion, synthesis, and modulation.

BALs have two major uses: in clinic as bioartificial liver support system (BALSS) to provide a short-term support for liver failure patients and in *in vitro* experimentation as a model system for therapeutic and toxicological studies.

BALs were developed as a promising approach for the treatment of patients with acute and fulminant hepatic failure. They don't offer a long-term nor a permanent substitute for an individual's liver. They support liver functions for a relatively short period of time and are intended to be used either as a bridge to a transplant or as a temporary support to allow the native or post-transplant liver to recover.

BALs with homogeneous and stable *in vivo*-like microenvironment are further employed as valid tools to investigate the basic biology of hepatic tissue development, to study liver diseases, to develop therapeutic strategies for drug-screening applications, to assess hepatic pathways of drug biotransformation, and to evaluate both

therapeutic and toxicological effects of various drugs and chemicals on hepatic metabolism (Salerno et al. 2013). The feasibility of BALs as good and achievable model systems for *in vitro* studies represents an alternative and/or complementary methods or procedure to *in vivo* animal experimentation. BALs as *in vitro* model systems allow the reduction of the number of laboratory animals and provide a faster and more cost-effective way of analysis. The use of human hepatocytes is the only system for a rapid, accurate, and highly specific evaluation of effects taking account of the species differences in liver response, substrate specificity, and enzyme induction between man and animals.

Critical issues in the design of a BAL are the configuration, the cell sourcing and density, the choice of the material for cell adhesion, the oxygenation and the gas exchanges, the mass transport of nutrients and catabolites, the scale-up, and the regulation and safety (Stevens et al. 2014). A successful BAL requires favorable culture conditions to maintain cell viability, functionality, and differentiation in the time. As liver cell sources, primary hepatocytes, either human or of xenogeneic derivation, human-immortalized hepatoma cell lines, hepatic progenitors, and intrahepatic or extrahepatic stem cells could be used.

Primary human hepatocytes represent the gold standard for their clinical safety and high liver-specific activity; however, their limited availability makes them unsuitable for clinical application and large clinical studies. Most systems are using xenogeneic cells of porcine origin which are more easily available; nonetheless the metabolic compatibility is not assured, and the transfer of xenogeneic virus and immunological reactions represent a potential risk. Human-immortalized hepatoma cell lines have the advantages of unlimited availability and good practicability, but they have low liver-specific activity and cancer-like cell metabolism. A large number of studies have utilized human liver-derived stem cells including fetal liver stem cells (hepatoblasts) and liver stem cells (oval cells) to generate primary hepatocytes; because of their rarity within the liver tissue, until today it is impossible to expand and differentiate

them to a sufficient cell mass. Other studies have induced extrahepatic stem cells, embryonic or adult stem cells, to differentiate into hepatocyte-like cells; although the pluripotent stem cells may be a suitable alternative to hepatocytes, their clinical use is limited by ethical concerns, for the first of them, and the risk for tumor development for both. A promising approach is in the use of induced pluripotent stem cells (iPSC) that are adult stem cells reprogrammed for their pluripotency by genetic manipulations (Lee and Cho 2012).

In an effort to recreate the interactions between parenchymal and non-parenchymal cells, hepatocytes have been co-cultured with several liver non-parenchymal cells such as endothelial cells, fibroblasts, stellate cells, and Kupffer cells, showing remarkable liver-like structure and functions.

Several types of BALs were developed by using cell suspensions, alginate beads, microcarriers, microcapsules, organoids, porous spheroids, collagen sandwich, and matrices.

To maintain hepatocyte functions and polarity, it's advantageous to mimic the matrix surrounding the hepatocytes in the sinusoid of the natural liver. To this purpose three-dimensional matrices or sandwiches configuration are the best environments for the long-term maintenance of viability, functionality, and differentiation state.

Polymeric membranes in flat sheet and in hollow fiber configurations are widely used as supporting materials for the design and development of BALs.

Membranes offer a substratum for adhesion of anchorage-dependent cells like the hepatocytes. Morphological characteristics (e.g., pore size, porosity, roughness) and physicochemical and mechanical properties of the membrane surface (e.g., wettability, surface free-energy parameters, Young's modulus) affect cell adhesion and the maintenance of cell viability, functionality, and differentiation in the time. Membranes with adequate molecular weight cutoff (MWCO) ranging from 70,000 to 100,000 Da represent a selective barrier for the compartmentalization of cells in nano- and microstructured environment ensuring immunoisolation and immunoprotection in allo-

xenogeneic implants and protection of cells from shear stress damages. Furthermore, the selective transport properties of membranes ensure a selective transport and an adequate mass transfer of molecules, nutrients, metabolic products, and endogenous and exogenous toxins as well as gas exchange from/to patient's blood or plasma and to/from the cell compartment.

The use of flat membrane bioreactors allows for control of the internal flow distribution and perfusion of all cells under a stable oxygen and nutrient gradient. The main drawbacks of a flat configuration are the difficulties to build a system with a sufficient cell density and an optimal ratio between the low surface area and the volume of the system. Most devices tested clinically employ hollow fiber membrane cartridges. In this configuration, the cells are compartmentalized, in the intralumen or in the extralumen of hollow fibers, and isolated from blood or plasma by the semi-permeable membrane with a proper molecular weight cutoff. However, the main drawbacks of a hollow fiber configuration concern inherent physical limitations including mass transport across the fiber wall and the hepatocyte mass, a limited total diffusion surface area, and an increased diffusion distance (Bao et al. 2011). The design of a successful BAL configuration could be optimized by modelling study in order to predict and verify the performance of the proposed configuration in terms of mass transport and cellular reaction rates.

Bioartificial Liver (BAL) Devices

► Bioartificial Liver Support System (BLSS)

Bioartificial Liver Support System (BLSS)

Simona Salerno
Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Synonyms

Bioartificial liver (BAL) devices; Biohybrid artificial liver systems; Cell-based liver support systems; Extracorporeal BALs; Temporary liver support systems

Bioartificial Liver Support System (BLSS) is a bioartificial liver that supports liver functions. In contrast to purely artificial or nonbiological liver support systems in which detoxification process is based on the principle of adsorption and filtration, such as hemodialysis, hemoperfusion,

hemofiltration, and plasmapheresis, bioartificial devices incorporate a functional cell component. This latter is constituted by living and metabolically active hepatic cells, or hepatocytes, which are able to fully replace the specific functions of the *in vivo* native liver, including biotransformation, synthesis, and modulation in addition to detoxification and excretion. The liver is a vital organ with a wide range of functions in synthesis, detoxification, and regulation; hence, its failure constitutes a life-threatening condition that in most cases can be overcome by orthotopic liver transplantation. Owing the shortage of donor organs, a variety of alternative treatments was developed to replace some of the liver's function in case of liver failure. BLSSs are expected to increase spontaneous recovery or at least improve patient survival until transplantation is possible.

BLSSs employ hepatocytes as *implantable systems* or *extracorporeal systems* (De Bartolo and Bader 2002).

Implantable systems are tissue-engineered constructs proposed as potential permanent BLSSs for *in vivo* liver regeneration. They include hepatocytes on coated microcarrier beads, within microencapsulated gel droplets, within biodegradable polymeric membranes, or as spheroid hepatocyte aggregates. They however require a prolonged period for intraperitoneal engraftment and vascularization, and their potential to provide long-term hepatic support is still in a very preliminary and experimental phase and untested yet in clinical trials.

Extracorporeal systems provide metabolic support for a relatively short time and for the treatment of acute liver failure and patients for which the orthotopic liver transplantation is the only effective therapy. Such systems serve as a bridge to solid organ transplantation or as a temporary support to allow the native and/or post-transplant liver to regenerate and/or recover properly. They are not invasive to the body: a shunt veno-venous or arterio-venous is required to connect the patient to the device. Blood is removed from the vein and circulated through the device where it is processed by living liver cells and then returned to the patient using a dialysis-type procedure. In some devices the blood plasma

removed from the patient is separated from the other constituents by plasma separators before it circulates through the device. Extracorporeal BLSSs include hepatocytes in suspension as aggregates/spheroids or in adhesion to matrices and/or membranes into a bioreactor and may be recharged with fresh hepatocytes for both a continuous or intermittent use.

In the design of BAL devices, critical aspects have to be taken into account such as the cell source and density, the culture condition and the long-term maintenance of well-differentiated hepatocyte functions, the oxygenation and the mass transport, and the configuration and the scaling-up of the systems.

Several types of extracorporeal BLSSs with different configurations have been developed: in packed bed, flat membrane sheet, and hollow fiber membrane systems (Morelli et al. 2010; Stevens et al. 2014). The flat membrane bioreactors allow a high-density cell culture under sufficient oxygenated conditions; however, they present some disadvantages such as the complex up-scaling of large flat plates. Most of the BLSSs are composed of hollow fiber cartridges with different polymeric membranes. Hepatocytes are loaded in the extralumen space or injected into the lumen of the hollow fiber membranes. Some of them comprise more independent but interwoven capillary systems in a three-dimensional network for medium inflow, medium outflow, and oxygen/carbon dioxide exchange (Sauer and Gerlach 2002).

In both the implantable and extracorporeal systems, membranes serve as immunoprotective barriers against host defenses. Immunological rejection is reduced by means of membranes with molecular weight cutoff (MWCO) of 70,000–400,000 Da which act as immunologic barrier between the patient's blood and hepatocytes; thus, xenogeneic or allogeneic implants may be used without an immunosuppression therapy.

The selective transport properties of membranes ensure a selective transport and an adequate mass transfer of molecules, nutrients, metabolic products, endogenous and exogenous toxins, as well as gas exchange from/to the patient's blood or plasma and to/from the cell

compartment. Furthermore, membranes offer a large surface area for adhesion of anchorage-dependent cells like the hepatocytes, affecting the maintenance of cell viability, functionality, and differentiation in relation to membrane morphological characteristics (e.g., pore size, porosity, roughness) and physicochemical and mechanical properties (e.g., wettability, surface free energy parameters, Young's modulus).

Several extracorporeal systems have undergone extensive animal testing and are currently investigated in the early stages of human clinical trials (Zhao et al. 2012). A series of studies showed that BLSS devices reduced mortality in acute liver failure cases.

Bioartificial Organs and Tissue

Artificial organs and tissues composed of cells supported by engineered extracellular matrices such as biomaterials or scaffolds in a suitable culture environment. These constructs are produced by applying principles from different established disciplines like engineering, chemistry, biochemistry, biology, and medicine, with the purpose to repair, replace, preserve, or improve the functions of damaged organs or tissues and as a possible alternative to the growing demand for their transplantation. Besides their *in vivo* application, human organs and tissue could be used as model systems for drug screening and testing and as valid tools to investigate the basic biology in *in vitro* research.

The new and functional living organs and tissue are fabricated using living cells, which are usually associated with a matrix or scaffold to guide the tissue and organ development, in a metabolic and physic microenvironment under tightly controlled conditions, such as bioreactors, for their maturation step.

The source of cells must be easily accessible, with a high proliferative capacity and ability to differentiate into the required cell type. Cells can be obtained from a fragment of adult tissue (primary cells) or from multipotent stem cells. They could be of autogeneic, allogeneic, or xenogeneic origin accordingly as they are from the same organism, from a donor of the same species, or from a different species, respectively. The

autologous primary cells have the advantage to avoid immuno-rejection and/or transmission of infective agents; however, only some of them present a high proliferative capacity. The use of embryonic stem cells (ESC) is very attractive though limited by ethical issues and their tumorigenic capacity. The isolation of adult (ASC) or mesenchymal (MSC) stem cells offers good alternative for their ability to activate and differentiate into multiple tissue cell types. Induced pluripotent stem cells (iPSC), which are ASC reprogrammed for their pluripotency by genetic manipulations, have been recently described as a new source of cells to regenerate tissues.

Biomaterials and scaffolds provide the appropriate biochemical and biomechanical cues for cell attachment and proliferation by mimicking the extracellular matrix (ECM) for cells. Due to their interaction with living cells, they must be biocompatible, nontoxic, and pharmacologically inert. These biomaterials can be permanent or biodegradable and made of synthetic or natural polymers or a composite network of both. The natural biological ECM, in addition to mechanical integrity, contributes in the development, maintenance, and regeneration of tissues, and it is itself a dynamic structure actively remodeled by the cells with which it interacts. Taking into account this consideration, the design characteristics of biomaterials and scaffolds are major challenges for materials scientists and should be considered at a molecular chemical level. Thus, new strategies are focusing on the development of interactive biomaterials that, by cell-material interactions, are able to activate, stimulate, and trigger cellular specific responses like cell proliferation and/or differentiation of embryonic and/or progenitor cells, driving the self-tissue formation and organization into a 3D construct. ECM-specific molecular structures or specific receptors and anchorage sites, as well as growth and differentiation factors, could be incorporated into cell support components to more closely replicate the native environment of the cells (De Bartolo et al. 2012). Composites of synthetic or natural polymers with bioactive ceramics or certain glasses can be designed to yield materials with a wide range of strengths and porosities for the engineering of hard tissues (Furth and Atala 2014).

After the cell seeding onto scaffolds, the maturation of an organ- or tissue-engineered construct takes place in bioreactors. Such systems facilitate the reproducible growth and production of bioartificial constructs under tightly controlled conditions, overcoming the limited seeding efficiency and poor transport of nutrients, oxygen, and wastes of the static cell culture conditions. The control of mass transport and gas exchange is particularly required for the development of highly perfused and oxygenated bioartificial organs, such as the liver and kidney. On the contrary, low oxygen tension is essential to improve the functions of engineered cartilage or to mimic the normal micro-environment or “niche” for stem cells. Furthermore, bioreactors may be used to enhance tissue formation through mechanical stimulation of the bone, cartilage, blood vessels, and skeletal and cardiac muscles. In particular, a pulsatile flow is helpful for the maturation of blood vessels, while a mechanical stretch strengthens engineered muscles (Furth and Atala 2014).

Scaffold-based tissue engineering has led to significant results in the reconstruction of various tissues. Small parts of bioartificial tissues (i.e., skin, cartilage, bone, blood vessels, corneas, urinary bladder, left mainstem bronchus, and trachea) have been successfully developed in experimental animals and approved either for human use or in clinical trials (Vacanti 2010; de Mel et al. 2012).

Currently, tissue engineering only offers the possibility of recovering lost function, while the formation of whole organs and tissues similar to the natural ones is still not a reality because of the difficulty in providing vascularization, innervation, and the same signals of the extracellular matrix.

Recently, novel approaches that do not rely on artificial scaffolds have been pursued. The most promising ones utilize matrices of decellularized organs or bioprinting-based technologies. The xenogeneic whole-organ *decellularization* allows the production of complex three-dimensional extracellular matrix bioscaffolds of the entire organ with preservation of the intrinsic vascular network. These bioscaffolds can then be recellularized by autologous cells to create

potentially functional organ constructs. With this strategy, it has been possible to obtain organs such as the heart, liver, trachea, and lungs (He and Callanan 2013). The so-called organ printing is based on multicellular self-assembly by a computer-aided bioprinting technology. 3D printers combined with image-processing software, operating with *bioink* particles of spheroidal cell aggregates and *biopaper* of biocompatible ECM hydrogels, are able to form and build complex 3D living structures with complete control of the internal structure, including a vascular tree (Marga et al. 2012).

Bioartificial Organs, Membrane Operations

Artificial organs realized by taking advantage of membrane technology and operations. They consist of functional cells supported by polymeric membranes as scaffold, in a suitable culture environment in which cells are maintained and induced to perform all the specific functions of the *in vivo* native organ. In most cases they incorporate cells into membrane bioreactors.

Organ level tissue engineering requires a biomimetic microenvironment that provides substrates for cell maintenance and proliferation and signaling cues directing morphogenesis and cell differentiation toward tissue-specific structures and phenotype. The choice of biomaterials with high biostability and biocompatibility and with specific physicochemical, mechanical, and morphological properties on the basis of the targeted tissues or organs is crucial for successful bioartificial constructs.

Progress in membrane technology and in membrane operations in understanding and controlling micro- and nano-properties and selectivity in transport phenomena currently offer new interesting opportunities for the design of bioartificial organs. Membranes in flat sheet and in hollow fiber configurations serve to house cells, supporting their growth and adhesion and directing their reorganization in a three-dimensional architecture.

Moreover membranes, exposing cells to an adequate perfusion and oxygenation, are able to guide cellular differentiation and functions (Salerno et al. 2013a).

The first concept of membrane-based bioartificial organs was based on the development of implants containing living xenogeneic or allogeneic cells enclosed and/or encapsulated in a selective membrane barrier for cell transplantation. In such compartmentalized system, membranes act as a selective barrier for immune isolation of cells. They admit the unhindered passage of oxygen and small molecules required for cell metabolism and the release of bioactive components to the host. In particular, the selective transport properties of membranes ensure the transport and an adequate mass transfer of nutrients, metabolic products, growth factors, endogenous and exogenous toxins as well as gas exchange. In the meantime, membranes with adequate molecular weight cutoff (MWCO) ranging from 70,000 to 100,000 Da restrict the passage of larger cytotoxic agents of the immune defense system, allowing the immune isolation and immune protection of cells in allogeneic and xenogeneic implants. The use of membranes as a selective barrier eliminates the need of chronic immune suppression in the host and allows the use of allogeneic and xenogeneic cells, thus avoiding the cell-sourcing constraints. Furthermore, the compartmentalization of cells in nano- and micro-structured environment ensures and protects cells from shear stress damages in membrane bioreactors (Drioli and De Bartolo 2006). Recent advances in mesenchymal stem cell biology and in their expansion and differentiation have made possible the use of autologous cell source to avoid the immuno rejection drawback.

In bioartificial organs, polymeric membranes not only act as selective and immune protective barriers, but they also play a crucial role in cell adhesion and cell interaction mimicking the extracellular matrix (ECM) with which cells interact. A proper cell-material interaction could trigger cell growth, migration, proliferation, differentiation, and functional activation, thus allowing the organization of cells in a three-dimensional architecture and the maintenance of cell viability and

functionality. At the same time, an inappropriate cell-material interaction could trigger programmed cell death or apoptosis.

New biofabrication approaches to create and develop complex organotypic and organomimetic systems reckon with molecular, architectural, and biophysical basis of tissue principles which are tightly related to developmental biology and morphogenesis. Recent advances in the molecular cell biology of morphogenesis, as well as in stem cell biology, will aid in the design principles and architecture for tissue engineering and regeneration (Ingber 2014). Organs are made of tissues and tissues are made of cells. To make and tailor bioartificial organs is necessary to start from tissue engineering and, therefore, from cell-material interactions.

The choice of ideal scaffold materials, optimum cell source, and well-defined tissue culture conditions is required for the realization of safe and confident bioartificial substitutes for clinical application.

Membranes are eligible scaffolds for tissue engineering and bioartificial organs. The majority of membranes for the realization of organ membrane systems are manufactured from homogeneous polymer solutions by phase inversion. This technique is a very versatile process for the synthesis of membranes from different polymers, also biodegradable, and with a wide variety of modulated morphological, physicochemical, mechanical, and transport properties depending on the target bioartificial organ.

Porous membranes with specific *pore size* and *porosity* influence cell adhesion and the transport and/or diffusion of nutrients and metabolites, to and from cells. Morphological and physicochemical surface properties, such as *roughness*, *wettability*, and *free energy parameters*, affect cell adhesion and consequently the cell shape either indirectly, by controlling the adsorption of proteins, or directly, by guiding cell spreading and cytoskeleton rearrangements. *Topographical cues*, including grooves, ridges, wells, and nodes, drive the cell orientation and migration and the three-dimensional architecture of the growing bioartificial organ. *Mechanical properties* play in control of cell growth, differentiation,

motility, and apoptosis. The signals that are actually responsible for dictating tissue pattern are often mechanical in nature, such as compression on the bone, shear stress on blood vessels, and tension on muscles. The choice of materials with specific mechanical properties is strictly related to the target tissue or organs: the bone (hard tissues) necessitates stiff matrices; tendons, ligaments, skin, fibrous tissues, muscles, nerves, and blood vessels (soft tissues) need more elastic and flexible scaffolds. Since both embryogenesis and mesenchymal differentiation toward the formation of new organ rudiments take place under mechanical tension and compression, differentiation of embryonic and mesenchymal stem cells is strongly influenced by substrate stiffness. On polymeric membranes, an enhanced tensile modulus and strength and a high porosity are able to promote capillary development by endothelial cells, thus favoring the vascularization in organotypic membrane systems (Salerno et al. 2011).

To tailor the material bioactivity and to more closely replicate the native and natural microenvironment of the cells, membranes and biomaterials could be modified by incorporating biomolecules and/or ECM-specific molecular structures. They could also include structural units for the targeted controlled release of bioactive molecules as growth factors or cytokines to be released at the right time and at the right place and to mimic natural signaling pathway. Moreover, the design of *biodegradable membranes* with a programmed and predictable biodegradation rate consistent with the tissue formation rate is useful for implantable bioartificial constructs. The research strategies for the next 20 years will focus on the implantation of bioartificial tissues and the induction of the *in situ* regeneration and self-repairing of damaged organs and tissues (De Bartolo et al. 2012).

Although the engineering of fully functional bioartificial organs for transplantation is not yet a reality for the difficulty in providing vascularization and innervation, bioartificial tissues with increasing complexity reach clinical application nowadays. Advances in biomaterials and in stem cell biology have made possible the realization of

tissues and organotypic bioartificial systems for clinical as well as basic research applications. Membrane systems supporting and stimulating cell differentiation and proliferation have been involved in the biofabrication of active substitutes in static and dynamic conditions (Salerno et al. 2013a, b). The dynamic culture models such as the *membrane bioreactors* may simulate the *in vivo* complex physiological environment through the fluid dynamics modulation and the selective membrane transport, ensuring an adequate mass transfer of nutrients and metabolites. In such microenvironment a constant turnover of tissue culture medium augments the gas and nutrient exchanges, which together with the complete fluid dynamics control ensures the long-term maintenance of cell viability and functions. Membrane bioartificial organs could be used as implantable or extracorporeal devices for tissue loss or organ failure and for the designing of *in vitro* model systems for drug screening and diagnostic applications. Examples of membrane bioartificial organs are the membrane bioartificial liver and the bioartificial liver support systems.

Introduction

Bioartificial synthetic membrane is a synthetic enclosing or separating membrane that functions as a selectively semipermeable barrier of artificial organs such as artificial livers, artificial kidneys/dialyzers, and artificial lungs/blood oxygenators. Bioartificial synthetic membrane can separate the contents (e.g., cells) and components of the recipient's immune system (Nyberg et al. 2003). The importance of a bioartificial synthetic membrane is suggested by the rapid influx of ultrafiltrate components and the reservation of functional cells (e.g., human primary renal proximal tubule cells of bioartificial kidneys), with the inhibition of undesired back diffusion into the recipient's system (Ni et al. 2010).

Generally, bioartificial synthetic membranes that are in contact with biological fluids should prevent any type of infection and immune

response, thrombus formation, and other biological response that could affect the properties of the fluid (Stamatialis et al. 2008). The approaches to the development of biocompatible membranes include three categories: (1) optimization of synthetic polymer, (2) modification of material surface, and (3) construction of biomimetic membrane surfaces (Kawakami 2008). So far, a variety of materials have been used for bioartificial synthetic membranes, including polymethyl methacrylate, polydimethylsiloxane, polysulfone, polyethersulfone, poly(ethylene oxide), and poly(vinyl alcohol). Alternatively, membrane surface properties can be modified to suppress immune response, and prevalent methods are comprised of plasma etching, corona discharge, UV irradiation, and covalent attachment (Yoshida et al. 2006).

Nondegradability is an important factor for bioartificial synthetic membranes. Unexpected swelling and leaching can result in reduced fracture strength and elastic modulus of the material, leading to static fatigue or crazing (Stamatialis et al. 2008).

It is very important that bioartificial synthetic membranes can have identical functions as the organs, which is closely related with membrane structure. The structure parameters of membranes generally include thickness, pore size, porosity, and so on. For instance, in artificial kidneys, the pore sizes should be well controlled in order to prevent leakage of useful proteins in blood such as blood corpuscles and albumin (molecular weight 69,000 Da) while removing harmful substances (Kawakami 2008). Microdomain structure is also important for interaction of membranes with seeded cells. Differentiated epithelia of human primary renal proximal tubule cells have been found on the optimal membrane materials with/without coatings (Ni et al. 2010), and the concept of developing asymmetric membranes is suggested for bioartificial synthetic membranes.

Biobutanol Recovery from Biomass Fermentation Broth

Wanqin Jin

State Key Laboratory of Materials-Oriented Chemical Engineering, Nanjing University of Technology, Nanjing, China

Biobutanol recovery from biomass acetone-butanol-ethanol (ABE) fermentation broth by pervaporation is a process that couples ABE fermentation with in situ pervaporation recovery acetone, butanol, and ethanol from fermentation broth.

During the past decade, there has been an increasing interest for the production of biofuels from renewable resources because of growing concerns about global warming and increasing consumption of crude oil. Butanol, as compared to ethanol, is less volatile and explosive, contains more energy, and can easily mix with gasoline in any proportion. In addition, butanol can be used directly or blended with gasoline or diesel without any vehicle retrofit, since the air to fuel ratio and the energy content of butanol are close to gasoline (Qureshi and Ezeji 2008). Biobutanol is produced

Biobutanol Recovery from Biomass Fermentation Broth, Fig. 1 ABE fermentation-pervaporation-coupled process

from renewable resources (biomass) by acetone butanol ethanol (ABE) fermentation process. However, usually the maximum concentration of total solvents (ABE) do not exceed 20 g/L due to the end-product inhibition on microbes, resulting in high energy cost to recover ABE from the dilute fermentation broth by distillation. Therefore, several in situ product-removal technologies, such as adsorption, gas stripping, liquid-liquid extraction, perstraction, pervaporation, and reverse osmosis, have been developed. These technologies could be coupled with ABE fermentation process to reduce the effect of product inhibition and improve the sugar utilization and solvent productivity (García et al. 2011).

Pervaporation (PV) is a membrane process for liquid separation, in which a polymeric or inorganic membrane usually serves the separating barrier. The application of PV for butanol recovery from fermentation broth is based on the selective permeation of organic compounds through the membrane when the nature of the membrane is hydrophobic. PV is especially effective for the system in which the concentration of the targeted species is low; for instance, the butanol content in the fermentation broth is very low. Furthermore,

the pervaporation process is energy efficient and it is harmless to the fermentation broth.

PV membranes can be made from either polymeric or inorganic materials, even both of them (Qureshi and Blaschek 1999). The polymeric pervaporation membranes for extracting butanol from fermentation broth include polydimethylsiloxane (PDMS) membranes, poly [1-(trimethylsilyl)-1-propyne] (PTMSP) membranes, poly(ether block amide) (PEBA) membranes, liquid membranes, other modified polymer membranes, as well as porous polypropylene (PP) membranes and polytetrafluoroethylene (PTFE) membranes. Among them, the commonly used PDMS membranes with good selectivity and stability are regarded as the most potential PV membranes for butanol recovery application. The typical inorganic membrane for PV is hydrophobic zeolite membrane, such as ZSM-5 and silicalite-1 membrane. The process of biobutanol recovery from biomass ABE fermentation broth by pervaporation is also called ABE fermentation-pervaporation-coupled process; its conventional flow chart is shown in Fig. 1 (Liu et al. 2011). A pervaporation membrane module is connected to the fermentor, and the ABE solvent

can be selectively and continuously removed from the fermentation broth and then concentrated in the membrane downstream side. As result, the ABE concentration in the broth is kept at low level to facilitate the continuous fermentation process as well as enhance the solvent productivity. In addition, a microfiltration/ultrafiltration unit can be alternatively installed before the pervaporation module, in order to retain microbes and avoid the biofouling of pervaporation membranes.

Biocatalyst Recycling by Membrane Operations

Yamini Satyawali¹, Ehiازه Augustine Ehimen² and Winnie Dejonghe²

¹Separation and Conversion Technology, Vlaamse Instelling voor Technologisch Onderzoek (VITO), Boeretang 200, Belgium

²Separation and Conversion Technology, Flemish Institute of Technological Research (VITO), Mol, Belgium

Owing to current industrial demands for environmentally friendly solutions and cleaner

technologies, the end-of-life purification techniques that were applied for the product streams are being replaced with integrated process solutions in closed systems. Exhibiting high activities and selectivity difficult to achieve with chemical catalysts, biocatalysts have been regarded as ideal catalysts. The widespread use of biocatalysts in industrial processes is however largely impeded by their unfavorably high economic costs. The recycling of the expensive biocatalysts is therefore an important goal in applied biocatalysis, which would in turn promote the development of industrial enzyme-mediated processes.

Membrane filtration is an essential tool in the biotechnological industry and appears to be particularly useful for the purification and concentration of proteins. Membrane technologies could therefore be applied to achieve this goal of biocatalyst recycling. The application of membrane technologies in the field of biocatalyst (i.e., enzyme and whole cell)-mediated conversions could aid in achieving process simplification, as well as facilitating a recycling and reuse of the biocatalysts, and in reducing the process costs and could be a separation step for the components of the process effluent stream. The membrane retention and enzyme recycling methods described here are different from systems where the enzymes are immobilized on or entrapped in a membrane. The use of membrane technologies for biocatalyst recycling in biochemical processes however depends on a number of important features of the membranes employed.

Membrane processes can be differentiated on the basis of the size and geometry of the particles which are aimed to be retained (and recycled), for example, the use of microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO) techniques. With their ability to retain the biocatalytic entities and macromolecules (i.e., whole cells and enzymes) with dimensions between 8–800 and 0.5–8 nm, UF and NF membranes are most widely applied for biocatalyst recycling (Dijkstra et al. 2002).

Most UF and NF membranes are asymmetric membranes, with the pore sizes on the solute side

Biocatalyst Recycling by Membrane Operations,

Fig. 1 Biocatalyst membrane recycling schemes via (i) dead-end filtration and (ii) Cross-flow (loop) techniques

of the membrane smaller than those on the permeate side, which in turn largely prevents membrane clogging. The membrane stability under different operational conditions is also a very important factor which must be considered, since it indicates the potential biocatalytic processes which the selected membranes can be suitably applied for. This includes a consideration of the various possible interactions that the different reacting components and intermediates in the conversion process could have with the membrane surface. Unfortunately, data concerning such aspects must still largely be obtained by empirical investigations, since extensive data for most membranes is still lacking and not widely available.

The molecular weight cutoff (MWCO), which is defined as the molecular weight at which 90 % of the solutes are retained by the membrane, is usually used as the main quantitative criterion for the characterization of the membrane retention. It should however be remembered that the pore size distribution, charge effects, hydrophilicity, hydrophobicity, and polarity (of the solvents) can also greatly influence the permeability and functioning of the membrane (Dijkstra et al. 2002). In addition, especially in the case of biocatalyst recycling, the molecular shape and characteristics are important factors when considering biocatalyst retention using membranes. For example, globular proteins are more efficiently retained by membranes compared to the retention of flexible

polymers having elongated chains (Dijkstra et al. 2002).

Two major schemes can be applied for the recycling of biocatalysts using membrane operations. These are the use of (i) dead-end filtration and (ii) cross-flow (loop) filtration as shown in Fig. 1.

With the dead-end filtration technique, the biocatalyst is isolated in the reactor and is retained using UF or NF membranes. The reactants are continuously pumped into the reactor with the product and unreacted substrates permeating through the membrane for forward processing. However, the accumulation of the catalyst (i.e., concentration polarization) near the membrane surface can occur using this method. Using the cross-flow technique, the potential catalyst concentration polarization issue can be prevented, since the reaction solution is continuously circulated through the reactor. This ensures that the membrane is continuously swept clean by the fluid cross-flow going past the surface which then minimizes the enzyme build up while allowing the products and unreacted materials pass laterally across the membrane.

Biochemical membrane reactors

A biocatalytic membrane reactor (also referred to as a biochemical membrane reactor) is a system or device that combines and utilizes the separation capabilities of membranes and the catalytic activities of whole cell or enzyme biocatalysts in one unit to facilitate the biochemical conversion of substrates into desired products and the selective removal of the products in a single process unit. The removal of the product components from the reaction site could in turn improve the conversion of the substrates by favoring the product formation reaction and is thus useful for reactions that are thermodynamically unfavorable or are product inhibited. The separation of permeable solutes can be achieved from the reaction mixture by the action of a driving force that is applied across the membrane. As a result of coupling the conversion reaction with separation, lower operating costs could therefore be achievable with this type of reactor design compared to the use of multiple reaction and product separation methods.

The complete retention of the biocatalyst within the reactor system is the most important requirement for the successful continuous operation of biocatalytic membrane reactors. Ultrafiltration membranes with a pore size distribution range (nominal molecular weight cutoff, NMWCO, of 500–100 kDa) are the most adequate for the retention of a majority of native or

modified enzymes (10–100 kDa) (Prazeres and Cabral 1994).

The biocatalyst is usually present in the reactor system in two forms: free or immobilized at the membrane surface or inside the membrane matrix pores. If the biocatalyst (i.e., enzyme) is present in its free form, its immobilization can be achieved by confining the enzyme to one side of the membrane unit. This can be facilitated by size exclusion, electrostatic repulsion, or enlargement via chemical or physical immobilization techniques onto an intermediate support (i.e., inert proteins and gels). As for the direct immobilization of the biocatalyst onto the membrane, this can be achieved by chemical binding, physical adsorption, or electrostatic attraction.

Ideally the products resulting from the biocatalytic process should permeate through the membrane pores either via a concentration gradient-induced diffusion or a pressure gradient-induced convection. This would in turn facilitate a continuous removal of products from the reaction media, a process which has been considered to be essential for biocatalytic membrane reactor concepts. The selection of the membrane unit to be incorporated into the reactor system must take into account the respective sizes of the enzymes, substrates, and products, as well as the chemical characteristics of the reacting species and of the membrane. Here, the solute rejection coefficient is an important membrane selection parameter for the reactors and should be zero and one for the products and the biocatalysts, respectively (Prazeres and Cabral 1994). This would allow for the product/coproduct permeation through the membrane and a complete retention of the biocatalysts inside the reaction system.

The configurations of biocatalytic membrane reactors can be categorized into two main types (Fig. 1) (Giorno and Drioli 2000):

1. The biocatalyst (i.e., whole cells, enzymes, or antibodies) are used in solution for the conversion of the substrate to the desired products in a reactor and further transported to a reaction vessel containing a selected membrane where

Biocatalytic and Biochemical Membrane Reactor, Fig. 1 Main configuration types for biocatalytic membrane reactors; (1) Conversion reactor combined with a

membrane unit, (2) Submerged membrane reactor with the membrane functioning as a catalytic and separation unit (Adapted from Giorno and Drioli 2000)

the biocatalysts (and unreacted substrates) can be recycled back to the conversion reactor, with the permeate selectively extracted from the reaction stream. Here, the biocatalytic membrane reactor system might consist of a conventional stirred tank reactor combined with a membrane-separation unit.

- The biocatalyst constituents are immobilized within the membrane of the matrix. Here, the membrane acts as a support system for the biocatalyst as well as a separation unit.

The membrane units of the membrane reactor system can comprise of membranes which have a flat sheet shape (i.e., arranged in a plate and frame module or a spiral wound module) or tubular (assembled in a tube and shell module) (Giorno and Drioli 2000).

Advantages and disadvantages of biocatalytic membrane reactors (Prazeres and Cabral 1994):

Advantages	Disadvantages
Possibility of developing continuous conversion processes	Unfavorable adsorption and enzyme poisoning issues
Improved control of reaction systems	Enzyme deactivation due to shear-related effects
Increased productivities	Concentration polarization
Contribute in a favorable shift of the reaction toward product side	Likely product/substrate inhibition at the membrane surface
Better conversion rates in product-inhibited reactions	Membrane fouling
Good product enrichment and concentration in process stream	Enzyme leakage
Facilitates control of the molecular weight of hydrolyzates	
Allows the conducting of multiphase reactions, without emulsification issues	
Useful refined research tool for studying enzyme mechanisms

Biocatalytic Hollow Fiber Membrane Reactor

Yamini Satyawali¹, Ehiازه Augustine Ehimen² and Winnie Dejonghe²

¹Separation and Conversion Technology, Vlaamse Instelling voor Technologisch Onderzoek (VITO), Boeretang 200, Belgium

²Separation and Conversion Technology, Flemish Institute of Technological Research (VITO), Mol, Belgium

Biocatalytic hollow fiber membrane reactor refers to biological or enzyme-mediated reactor systems which employ the use of hollow fiber membranes as a support for enzyme or cellular immobilization, biocatalyst, and substrate recycling and as a means of concentrating selected reaction streams. A hollow fiber membrane is a tubular-structured semipermeable membrane with a center called “the lumen” having diameters in the size ranges 50–6000 μm as seen in Fig. 1 (Bunch 1988). Such small diameters facilitate a large membrane area (i.e., active surface) per unit volume for the bioreactor system, as well as enable the operation of the processes at higher pressures (Katoh and Fumitake 2009).

Where the semipermeable membrane structure continues to the outer surface of the fiber, the matrix is considered to be uniform, and this type of fiber is termed isotropic. In cases where the semipermeable membrane only has a thickness of 0.1–0.5 μm and is surrounded by a more open structure, the fibers are called anisotropic (Bunch 1988). Although the open spongy structure of anisotropic fibers is often larger than most used enzymes and microbes that may be employed in bioreactors, before such biocatalysts can gain entrance to the matrix, the pores on the outer surface (shell side) of the hollow fiber need to be more than 1 μm in diameter (Bunch 1988). The outer pore sizes have however been noticed to vary from different manufacturers, even when comparing anisotropic hollow fibers having different filtration characteristics from the same company.

Configuration and Operation of Biocatalytic Hollow Fiber Membrane Reactors

The hollow fiber membrane modules can be either integrated into the biocatalytic reactor system in an external loop or incorporated directly into the bioreactor as a submerged membrane unit. In either case surface shear and/or backflushing is used to limit the membrane fouling (Fane, et al. 2002).

The immobilization and operation of the biocatalysts in the hollow fiber membrane reactors can be mainly classified into two categories (Hiromi and Norio 1984):

1. The biocatalyst (enzyme) solution may be introduced to the outside of the hollow fiber or to the inner lumen, with the substrate

Biocatalytic Hollow Fiber Membrane Reactor,

Fig. 1 Basic structure of a hollow fiber (Adapted from Bunch 1988)

Biocatalytic Hollow Fiber Membrane Reactor, Fig. 2 Schematic drawing of a hollow fiber membrane enzyme reactor (Hiromi and Norio 1984)

solution flowing on the opposite side of the membrane to the enzyme. The substrate molecules permeate the membrane and react with the entrapped enzyme. The product then diffuses back through the membrane to the substrate solution from where it can be further recovered (Fig. 2).

2. The enzyme solution is ultrafiltered into the porous region of an asymmetric hollow fiber membrane, or the hollow fiber is dipped into the enzyme solution so as to result in the absorption of the enzyme molecules into the spongy lumen. The substrate is then pumped into the reactor as previously highlighted. After the enzymatic conversion, the product permeates through the membrane into the lumen where it is collected.

Since the biocatalyst entrapment is not chemically modified, the kinetic behavior of enzymes in hollow fiber membrane bioreactors could be expected to be similar to those exhibited by free enzymes. However, with hollow fiber reactors in the first category, the substrate permeation into the membrane has been determined to be the rate-limiting step (Hiromi and Norio 1984). The rate of the biocatalytic reaction therefore tends not to

achieve maximum levels when compared to the same concentration range using free enzymes. This is since the actual substrate concentration in the “enzyme solution chamber” is always lower than the bulk substrate concentration as a result of the enzyme reaction.

Furthermore, the dependence of the catalytic rate on process temperature and pH for hollow fiber biocatalytic reactors are different from that of the free enzyme (Hiromi and Norio 1984).

Regardless of the mode of operation used, bioreactors can be run in parallel or in series. With the use of a parallel setup, defective reactors can easily be replaced without impacting the operation of the other reactors while the use of a series configuration could aid the use of different biocatalysts when sequential product transformations are required.

The control of the reaction temperature of the biocatalytic hollow fiber membrane reactors can be obtained by the use of a jacket with thermostated water circulated at the desired reaction temperature (as seen in Fig. 2), by the immersion of the bioreactor system in a temperature-controlled water bath or by containment in a constant temperature cabinet.

Advantages and Limitations with the Use of Hollow Fiber Biocatalytic Membrane Reactors

Potential Merits with the Use of Hollow Fiber Biocatalytic Membrane Reactors (Bunch 1988; Luther et al. 1992)

1. The possibility of immobilizing and using biocatalyst in one step
2. Potential regeneration of the biocatalyst
3. No enzyme losses or washout
4. Ease of process scale-up
5. Ease of reactor cleaning with lower sterilization requirements
6. Possibility for high volumetric productivity
7. Ease of enzyme dosing
8. Achieve homogenous catalysis with no limitation of substance transport
9. Lower bioreactor capital cost
10. Lower operational costs due to reduced need for further purification and immobilization
11. Less susceptible to contamination

Limitations with the Use of Hollow Fiber Biocatalytic Membrane Reactors (Bunch 1988)

1. The bioreactors usually require a particulate free media.
2. The use of organic solvents is usually restricted.
3. Fiber rupture.
4. Decreased stability of the biocatalysts.
5. Difficulty in recycling the membrane fibers.

Immobilization of enzymes

Biocatalytic membranes refer to the membrane systems which have been equipped to carry out biochemical reaction function via the integration of biocatalysts (i.e., whole cells and enzymes) on/within the membrane structure. Ultrafiltration, microfiltration, and dialysis membranes have been adapted to make biocatalytic membranes. These membranes can be activated so as to provide suitable conditions where the intended biocatalyst components can be coupled to it by physicochemical techniques.

The biocatalytic membranes are used in the bioreactor as a carrier or matrix for enzyme immobilization as well as a selective barrier. Such reactors are referred to as biocatalytic membrane reactors (BMRs). One of the interesting advantages of using biocatalytic membrane is the occurring of transport phenomena that are governed by convective flows. Convective flows are indeed the combination of diffusive and advective flows and thus are more intense than only diffusive flows. In case of conventional supports/carriers such as beads, only such diffusive flows govern the process rendering it less effective. In biocatalytic membrane there is generally a close contact between the membrane and the enzymes as a result of the enzyme immobilization. Such a close contact affects the properties of the immobilized enzymes depending both on the properties of the membrane and the enzyme itself. One of these enzyme properties, the pH optimum,

often shifts after the immobilization on a certain carrier. Predicting the direction of such a shift in pH optimum is sometimes possible by looking at the charge of the used carrier, but such predictions are uncertain and merely indicative. Furthermore, enzyme properties are affected by the used immobilization technique, which also will significantly determine the performance of the system. Therefore, the choice of immobilization technique and membrane is vital to obtain a high performing system, and both need attention when designing a new biocatalytic membrane system (Jochems et al. 2011).

Various immobilization techniques or chemistries are available for the manufacturing of biocatalytic membranes or for immobilizing enzymes on the membrane which can be realized via adsorption, entrapment, and chemical coupling methods such as cross-linking or covalent immobilization. The immobilization of the biocatalysts can also be achieved via gelation techniques. With the gelation method, the biocatalyst is immobilized in the gel layer formed during ultrafiltration due to the concentration polarization phenomenon (Gekas 1986).

For the preparation of the entrapped biocatalytic membranes, the phase inversion technique is usually applied. Here, the biocatalysts are introduced to the casting solution so as to contain the enzymes or whole cells in the polymeric structure of the resulting membrane. The use of the encapsulation method, which is similar to the entrapment method, has the biocatalyst contained in the liquid membranes formed via the emulsification of aqueous enzymatic phase with the organic membrane phase.

The cross-linking with bifunctional agents, i.e., glutaraldehyde (which is the most common bifunctional agent), is the simplest demonstrated method for the chemical immobilization of biocatalyst on membrane systems. Here, the biocatalysts initially need to be adsorbed onto/within the membrane structure. The formation of covalent bonds within the free amino groups in the enzyme molecule can then be achieved without any presence of reactive groups on the membrane.

The application of covalent coupling methods is obtainable with membrane systems which

contain reactive functional groups, i.e., hydroxyl (–OH), carboxyl (–COOH), and amine (–NH₂) groups. These reactive groups can be introduced on the membrane via the direct modification of the polymeric structure of the membrane or by the preparation of the membrane from suitable monomers which contain the desired functional groups.

[Modeling of biocatalytic membrane reactor](#)

For creating a biocatalytic membrane layer, the biological catalyst such as whole cells (bacteria, yeast, mammalian and plant cells) is inoculated into the porous membrane layer where they are grown, or bioactive molecules such as enzymes are immobilized within the membrane matrix or in a thin layer on the membrane interface of the membrane layer. A medium is flowing through

the biocatalytic, mostly asymmetric, plain, or cylindrical (hollow fiber) layer, supplying the cells with oxygen and nutrients or the enzyme with reactant(s) while the wastes and desired products are removed (Drioli and Giorno 1999). The performance of a hollow fiber or sheet bioreactor is primarily determined by the momentum and mass transport rate (Bird et al. 1960) of the key nutrients through the biocatalytic membrane layer. Thus, the operating conditions (transmembrane pressure, feed velocity) and the physical properties of membrane (porosity, wall thickness, lumen radius, matrix structure, etc.) can considerably influence the performance of a bioreactor, the effectiveness of the reaction. The limited transport of nutrients can cause serious damage in production. The introduction of convective transport is crucial in overcoming diffusive mass transport limitation of nutrients especially of the sparingly soluble oxygen. The starting balance equations developed by Navier and Stokes (Bird et al. 1960; Seidel-Morgenstern 2010; Nagy 2011) can be essentially simplified, and the momentum and the mass transport expressions can often separately be solved in the case of biocatalytic processes. The principle of the mass transport of substrates/nutrients into the immobilized enzyme/cells, through a solid, porous layer (membrane, biofilm) or through a gel layer of enzyme/cells, is the same. The structure and the thickness of this mass transport layer can be very different; thus, the mass transport parameters, namely, diffusion coefficient, D ; convective velocity, v ; the bioreaction rate constant; their dependency on the concentration; and/or space coordinate are characteristics of the porous layer and the nature of the biocatalysts. Some assumptions made for expression of the differential mass balance equation to the biocatalytic membrane layer are as follows: reaction occurs at every position within the biocatalyst layer; mass transport through the biocatalyst layer occurs by diffusion and convection; mass transport parameters (diffusion coefficient, convective velocity, bioreaction rate constant) are constant; and the process is steady state. Thus, the mass balance equation can be given for a plain membrane layer as follows, applying, e.g., the

Biocatalytic Membrane Reactor, Mass Transport in, Table 1 Expressions of the important biocatalytic reactions

Substrate inhibition:	$Q = \frac{r_{\max} c}{K_{Mi} + c + c^2/K_c}$
Substrate inhibition and competitive product inhibition:	$Q = \frac{r_{\max} c}{K_{Mi} (1 + p/K_p) + c + c^2/K_c}$
Competitive product inhibition:	$Q = \frac{r_{\max} c}{K_{Mi} (1 + p/K_p) + c}$
Noncompetitive product inhibition:	$Q = \frac{r_{\max} c}{(K_{Mi} + c) (1 + p/K_p)}$

Michaelis-Menten (MM) kinetics (c denotes the concentration):

$$D \frac{d^2 c}{dy^2} - v \frac{dc}{dy} - \frac{v_{\max} c}{K_M + c} = 0 \quad (1)$$

The source term can be different in biocatalytic reactions; the most often applied equations are listed in Table 1. The inhibited reaction can take place in both the enzymatic and microbial reactions.

Two important cases can be discussed, namely, when the outlet (at $y = \delta$) diffusive flow is zero ($dc/dy = 0$, no sweep phase on the permeate side, case A) and $dc/dy \neq 0$ at $y = \delta$ (there is sweep phase on the permeate side, case B). The mass transfer rates are given by Eqs. 2 and 3 for cases A and B, respectively, for first-order reaction as limiting case of MM kinetics (Nagy 2011):

$$J = \left(\frac{D}{\delta} \right) \frac{\left(\frac{Pe^2}{4} + \Theta^2 \right) \tanh \Theta + Pe \Theta}{\left(\frac{Pe}{2} \tanh \Theta + \Theta \right)} c^0 \quad (2)$$

with

$$\Theta = \sqrt{\frac{Pe^2}{4} + \vartheta^2}, \vartheta = \sqrt{\frac{k_1 \delta^2}{D}}$$

$$J = \beta \left(c^0 - \frac{\Theta}{e^{Pe/2} [(Pe/2) \sinh \Theta + \Theta \cosh \Theta]} c_\delta \right) \quad (3)$$

with ($c = c_d$ at $y = d$ and $c = c^o$ at $y = 0$; $Pe = nd/D$)

$$\beta = \frac{D}{\delta} \frac{([Pe/2]\tanh\Theta + \Theta)}{\tanh\Theta}$$

The mass transfer rates are given by Eqs. 4 and 5 for cases A and B, respectively, for zero-order reaction as limiting case of MM kinetics (k_0 denotes the reaction rate constant):

$$J = \frac{D}{\delta} c^0 \left[Pe - \frac{\vartheta^2}{Pe} \left(1 - \frac{1}{e^{Pe}} \right) \right] \quad (4)$$

and

$$J = \frac{D}{\delta} \frac{Pe}{2} \times \frac{e^{Pe/2}}{\sinh(Pe/2)} (1 - T) \left[c^0 - \frac{e^{-Pe}}{1 - T} c_\delta \right] \quad (5)$$

with

$$T = \frac{\vartheta^2}{Pe^2} (e^{-Pe} [1 + Pe] - 1); \vartheta = \sqrt{\frac{k_0 \delta^2}{Dc^0}}$$

The flow through this membrane is proportional to the transmembrane pressure drop and inversely proportional to the fluid viscosity (Darcy law, Eq. 6) (κ is the permeability and μ is the fluid viscosity):

$$v_M = -\frac{\kappa}{\mu} \frac{dp_M}{dr} \quad (6)$$

Then, one can get from Eq. 6, for capillary membrane, as:

$$\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial (rv_M)}{\partial r} \right) \equiv -\frac{\kappa}{\mu} \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial p_M}{\partial r} \right) = 0 \quad (7)$$

When Eq. 7 is integrated twice with respect to r with boundary conditions, at $r = r_o$ then $p_M = p_t$ and at $r = r_o + d$ then $p_M = p_e$, one gets the radial pressure and velocity distributions (Nagy 2011, pp. 178) within the membrane as:

$$p_M(r, z) = \frac{p_t(z) - p_e(z)}{\ln(1 + \delta/r_o)} \ln \frac{r}{r_o} + p_t(z) \quad (8)$$

$$v_M(r, z) = \frac{\kappa}{\varepsilon \mu} \frac{r_o}{r} \frac{p_t(z) - p_e(z)}{\ln(1 + \delta/r_o)} \quad (9)$$

The axial pressure distribution is given in entry “[Hollow Fiber Enzymatic Reactor, Modeling of.](#)”

Biocatalytic Membrane Reactor, Modeling of

Endre Nagy

Research Institute of Chemical and Process Engineering, University of Pannonia, Veszprem, Hungary

There are two main types of membrane bioreactors: (i) the system that consists of a traditional stirred-tank reactor combined with membrane separation unit and (ii) the membrane that contains the immobilized biocatalysts such as enzymes, microorganisms, and antibodies and, thus, acts as a support and a separation unit. The biocatalyst can be immobilized in or on the membrane by entrapment, gelification, physical adsorption, ionic binding, covalent binding, or cross-linking (Giorno and Drioli 1999; Cabral et al. 2001). Modeling of stirred-tank reactor, for chemical reactions in it, is known (Westertep et al. 1993). This can easily be adapted for biochemical reactions applying the reaction kinetics given in entry “[► Biocatalytic Membrane Reactor, Mass Transport in.](#)” The momentum and

mass, energy transport through membrane as a separation unit, starting with Navier-Stokes equation (Bird et al. 1960), strongly depend on the separation process used (Baker 2004; Drioli et al. 2006; Nagy 2011). Immobilizing biocatalyst in the porous membrane matrix of an asymmetric membrane or onto membrane interface, the membrane layer can act as an active catalyst and a permselective layer. The biocatalytic membrane modules (plane and frame, hollow fiber capillary, tube as well as spiral membrane modules) can be divided into three sections: feed and permeate fluid phases and the biocatalytic membrane layer itself. Modeling of a membrane process means the simultaneous treatment of every section starting with Navier-Stokes equations for momentum, mass, and energy (Bird et al. 1960) adapting them to the real operating conditions and completing them by source or sink terms (Seidel-Morgenstern 2010). The energy balance equation is mostly negligible in case of biochemical reaction; the process can be regarded as isotherm; accordingly the continuity (conservation of mass), momentum, and component balance equations (see Eqs. 1–4 in entry “► [Hollow Fiber Enzymatic Reactor, Modeling of](#)”) should be simultaneously or consecutively (mass transport does not affect the velocities of fluids) solved after suitable simplification of a real system. The cylindrical effect should be taken into account for capillary membrane when the ratio of the membrane thickness and the internal radius is larger than about 0.05. The second-order pressure gradient can be expressed by Eq. (1) (Nagy 2011, p. 225). From that the radial and the axial velocity distribution in the feed (lumen) and the shell side can easily be obtained.

$$\frac{d^2 p_t}{dz^2} = \frac{8u_o \mu \zeta}{r_o^2 \lambda (1 + \zeta) \sinh(\lambda L)} \frac{1}{\lambda^2} \{ \cosh[\lambda(L - z)] - \langle 1 + f(1 + \zeta) \rangle \cosh(\lambda z) \} \quad (1)$$

with $[r_k]$ denotes the outer radius of hexagonal arrangement of the hollow fibers; f is the fraction of inlet feed directed out through the shell (Nagy 2011)]

$$\lambda = \sqrt{\frac{16\kappa}{r_o^3 \ln(1 + \delta/r_o)}} \left(1 + \frac{1}{\zeta} \right)$$

and

$$\zeta = \left(1 + \frac{\delta}{r_o} \right)^2 - \left(\frac{r_k}{r_o + \delta} \right)^2$$

The mass transfer rates for constant parameters are given in entry “► [Biocatalytic Membrane Reactor, Mass Transport in](#)” for limiting cases. An analytical approach is recommended by Nagy (2011) for the general Michaeli-Menten kinetics or bioreactions with two substrates feeding on the two sides of the membrane reactor. This method can take into account the effect of the in-space and/or time variable or concentration dependent parameters on the process.

Synonyms

Catalytic membrane bioreactors with biocatalysts segregated within the pores of asymmetric membranes; Catalytic membrane reactors with biocatalysts segregated within the pores of asymmetric membranes

Polymeric and inorganic membranes with asymmetric structure have been used to segregate (by physical entrapment and adsorption) enzymes and microbial cells within the porous membrane structure (Drioli and Giorno 1999; Drioli et al. 1982).

Polymeric membranes have been cast with microbial cells in the casting solution using the phase inversion technique. A number of microorganisms can withstand high temperatures and organic solvents and have been entrapped in membranes. Microbial enzymes maintain their activity presumably because of cellular membrane protection. Cell-loaded membranes appear to be kinetically active and stable over a long period of time. It is noteworthy that cell entrapment can enhance microbial activity as compared to cell behavior in a homogeneous solution, an effect probably due to cellular membrane permeabilization as a consequence of the entrapment procedure.

Biocatalysts can also be entrapped in asymmetric membranes after their preparation, by cross-flow ultrafiltration, under operating conditions that promote fouling, where foulant molecules are the biocatalysts themselves. The retention of enzymes within the porous layer of the asymmetric membrane is very efficient when permeating

enzyme solution from porous to selective layer, where the pores in the selective layer are small enough to retain enzyme molecules but large enough to let products pass through.

Enzymes are not able to work at high concentration; hence, the amount of immobilized catalyst strongly affects reactor performance. When the substrate is transported by convection through the enzyme-loaded membrane, the residence time is an important parameter to optimize.

For systems where the substrate is transported by diffusion, quick graphical procedures are available in literature for evaluating the extent to which external and internal diffusion affects immobilized enzyme kinetics (Engasser 1978; Bailey and Ollis 1986). Suggested models can be used to predict reactor performances in the case of enzymes with relatively simple kinetics (such as α -galactosidase, invertase, glucose isomerase, urease, fumarase) and when the kinetic and transport parameters are known.

The dynamics of substrate conversion depends on enzyme kinetics as well as on mass transport conditions.

Asymmetric hollow fibers with selective layer either on the lumen side or on the shell side can provide an interesting support for immobilizing enzymes. Figure 1 shows the case where the enzymes are effectively immobilized or segregated within the spongy annular section of an asymmetric hollow fiber containing the selective layer on the lumen side.

In this configuration, the substrate solution can be circulated along the shell side of the membrane module and permeated through the enzyme-loaded membrane under an applied transmembrane pressure as driving force. As the substrate permeates through the membrane containing the enzyme, it is converted to the reaction product. If the molecular weights of substrate and products are small, both can permeate through the membrane. This means that the permeate recovered from the lumen side of the membrane contains both reaction product and unconverted substrate. Measuring the reduced substrate concentration (or the increased product concentration) in the permeate during time operation, it

Biocatalytic Membrane Reactors (BMR) with Biocatalysts Entrapped Within the Pores of Asymmetric Membranes, Fig. 1 Cross-section of BMR with enzyme entrapped within the porous support

is possible to calculate the reaction rate and the conversion degree.

If the enzyme is immobilized only within the pores and not on the membrane surface, the concentration of the substrate in the retentate stream does not change, because only the solution that permeates through the membrane contacts the biocatalyst. The substrate is then continuously recycled to the tank and fed to the reactor at constant concentration (Giorno et al. 2001).

If the enzyme is also present on the membrane surface, some decrease of substrate concentration in the retentate stream is also observed. A blank experiment may confirm that when no enzyme is present on the membrane, no conversion occurs.

The conversion degree can be calculated as follows:

$$\text{Conversion} = \frac{C_r - C_p}{C_r} \quad (1)$$

where

C_r = concentration of substrate in the retentate solution

C_p = concentration of substrate in the permeate solution

This gives the conversion at each passage through the membrane pores that basically work as high-throughput microreactors.

When the enzyme is also immobilized on the membrane surface, it is necessary to take into account the conversion of the substrate in the retentate solution, and then the total conversion is calculated as:

$$\text{Total conversion} = \frac{(C_r - C_p) + (C_i - C_r)}{C_i} \quad (2)$$

where C_i is the initial substrate concentration.

The reactor volume is represented by the void volume of the porous asymmetric membrane. Under convective flow, each macrovoid of the asymmetric membrane can work in conditions of continuous stirred tank reactor. If this assumption is applicable, the reaction rate equation can be derived by the balance equation at steady state:

$$QC_f - QC_p + v_r \cdot V = 0 \quad (3)$$

Resolving for v_r , the following is obtained:

$$v_r = \frac{Q(C_f - C_p)}{V}$$

where v_r is the reaction rate ($\text{mmol} \cdot \text{cm}^{-3} \cdot \text{min}^{-1}$); Q is the filtration flow rate ($\text{cm}^3 \cdot \text{min}^{-1}$); C_f and C_p are the feed and permeate concentration ($\text{mmol} \cdot \text{cm}^{-3}$), respectively; and V is the reactor volume (cm^3).

The general behavior of reaction rate and conversion as a function of residence time assumes the form qualitatively illustrated in Fig. 2.

Increasing the residence time means decreasing of the filtration flow rate (Q); therefore, reaction rate increases as long as higher residence time means more interaction between the substrate and the immobilized enzyme. After the residence time to saturate enzyme is reached, C_f and C_p in Eq. 3 are constant, and further increase of residence time (i.e., decrease of filtration flow rate) causes a decrease of the reaction rate (Mazzei et al. 2012).

Biocatalytic membrane reactors with covalent bound enzyme; Immobilized enzyme

Attachments of biocatalysts to membrane can result from ionic binding, cross-linking, and covalent linking. Since 1954, when protease was covalently bound to diazotized polystyrene, enzyme immobilization via covalent bonds has been an established immobilization technique, usually carried out by means of bi/multifunctional reagents, such as glutaraldehyde, (3-aminopropyl) triethoxysilane (APTES), 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC), etc.

The crucial aspect is the use of mild reaction conditions that do not denature the enzyme during the covalent bond formation.

When the extent of initial denaturation is acceptable in the economics of the process, enzymes bound to membranes can be used in continuous flow reactors.

Table 1 shows the protein functional groups involved in covalent bond with functional groups present or grafted on the membrane, in mild conditions.

Table 2 summarizes most commonly used cross-linking agents to bridge enzyme to functionalized membranes.

Hydrophilic, hydrophobic polymeric membranes as well as inorganic membranes can be used as support for covalent bound of enzymes.

Polymeric membranes based on natural materials, such as cellulose and its derivatives (regenerated cellulose, cellulose acetate, etc.) have been extensively used as support for the covalent immobilization of enzymes. Cellulose membranes can be activated by a variety of agents

Biocatalytic Membrane Reactors with Chemically Bound Enzyme, Table 1 Protein functional groups involved in covalent bond with membranes in mild conditions

Protein chemical group	Structure
Epsilon amino groups of lysine	 The structure shows the side chain of lysine: a four-carbon chain starting from the alpha-carbon (which is bonded to an amino group and a carboxylic acid group). The terminal carbon of this chain has an amino group (H ₂ N), which is circled in red.
Epsilon amino groups of arginine	 The structure shows the side chain of arginine: a three-carbon chain starting from the alpha-carbon (bonded to an amino group and a carboxylic acid group). The terminal carbon is part of a guanidinium group (C(=NH)NH ₂), where the terminal amino group (H ₂ N) is circled in red.
Beta and gamma carboxyl groups of aspartic and glutamic acids	 The structure shows the side chain of aspartic acid: a two-carbon chain starting from the alpha-carbon (bonded to an amino group and a carboxylic acid group). The terminal carbon has a carboxylic acid group (HO-C=O), which is circled in red.
Phenol ring of tyrosine	 The structure shows the side chain of tyrosine: a three-carbon chain starting from the alpha-carbon (bonded to an amino group and a carboxylic acid group). The terminal carbon is part of a phenol ring (benzene ring with an OH group), which is circled in red.
Thiol group of cysteine	 The structure shows the side chain of cysteine: a two-carbon chain starting from the alpha-carbon (bonded to an amino group and a carboxylic acid group). The terminal carbon has a thiol group (HS-), which is circled in red.
Hydroxyl groups of serine and threonine	 Two structures are shown. On the left is serine, with a one-carbon side chain ending in a hydroxyl group (HO-), circled in red. On the right is threonine, with a one-carbon side chain ending in a hydroxyl group (OH), circled in red.
Imidazole group of histidine	 The structure shows the side chain of histidine: a two-carbon chain starting from the alpha-carbon (bonded to an amino group and a carboxylic acid group). The terminal carbon is part of an imidazole ring, which is circled in red.
Indole group of tryptophan	 The structure shows the side chain of tryptophan: a three-carbon chain starting from the alpha-carbon (bonded to an amino group and a carboxylic acid group). The terminal carbon is part of an indole ring system, which is circled in red.

Biocatalytic Membrane Reactors with Chemically Bound Enzyme, Table 2 Bi/multifunctional reagents commonly used in enzymatic covalent immobilization

Cross-linker	Structure	Reactive chemical group
Glutaraldehyde (GA)		Aldehydic groups
(3-aminopropyl) triethoxysilane (APTES)		Ethoxyl and amino groups
Dimethylaminopropane (DAMP)		Amino groups
O, O'- Bis(2-aminopropyl)-polyethylene glycol 500 (bNH2PEG)		Amino groups
1,3,5-benzene tricarbonyl chloride (or trimesoyl chloride TMC)		Carbonyl chloride groups
1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC) <i>Spacer Arm 0.0 Å</i>		Carbodiimide group
Dicyclohexylcarbodiimide (DCC) <i>Spacer Arm 0.0 Å</i>		Carbodiimide group

to produce reactive centers for the covalent binding of enzymes. Its chemical structure is mainly composed of hydroxyl groups, and then the most common activation methods are based on the conversion of the hydroxyl groups into more reactive functional groups. In particular, carbonyl groups are very suitable for enzyme immobilization since they can react with primary amines from enzymes (ϵ -amino group of lysine residues) to form imine. The most used method of forming carbonyl groups onto the cellulose skeleton is periodate oxidation. The hydroxyl groups (secondary alcohol groups) of the glucose units are oxidized into

the corresponding aldehydes by means of sodium periodate (NaIO_4). The covalent binding of the enzyme can be achieved by direct reaction with the aldehyde-active groups on the membrane surface (Xiao-Jun et al. 2011) or via different spacers. The introduction of an appropriate spacer between the enzyme and the membrane often improves the performance of immobilized enzyme, such as enzyme stability and retained activity. Spacers of different lengths are generally introduced by using bifunctional agents such as diamines (esp. ethylenediamine, pentaethylenhexamine, etc.) that are coupled or activated with glutaraldehyde

Biocatalytic Membrane Reactors with Chemically Bound Enzyme, Fig. 1 Schematic representation of an enzyme covalently immobilized onto cellulose membrane

activated with periodate oxidation and a generic diamine spacer, n represent the number of CH_2 groups

before enzyme immobilization (Peng-Cheng et al. 2011). The reaction mechanism involves the amino groups of the enzyme and the aldehyde groups of glutaraldehyde on the membrane surface. The schematic representation of an enzyme covalently attached onto cellulose-activated membrane is reported in Fig. 1.

Poly(vinylidene fluoride) (PVDF) membrane has been used either for scientific research or industrial application in particular micro- and ultrafiltration process. The great interest to PVDF membrane is due to its extraordinary thermal, mechanical, and chemical resistance in addition to membrane-forming properties. Its structure consisting of repeated $-(\text{CH}_2-\text{CF}_2)_n-$ units confers to PVDF these good properties, but makes impossible enzyme immobilization on native PVDF in a covalent manner. This disadvantage can be overcome performing PVDF functionalization, in order to introduce on the polymeric membrane structure, reactive groups that can covalently couple with enzyme functional groups. Surface modification of existing PVDF membrane can be performed by coating or grafting. Coating modification is preferred when only an improved hydrophilicity of the membrane surface is required, but it is not useful as anchor point for enzyme immobilization because of the instability of the coated layer which interacts with the membrane merely by physical adsorption. More

interesting for enzyme immobilization is grafting modification which can introduce on the PVDF backbone functional chains that can be used for enzyme immobilization; in addition acting on degree of grafting and type of functional chain introduced, it is possible to affect or not affect membrane bulk properties as, for example, hydrophobicity.

Surface grafting can be performed by high-energy radiation techniques like plasma treatment, ozonation, and UV or by wet chemistry in harsh basic environment. For example, grafting of amino groups on PVDF membrane surface can be achieved by treatment at high pH and high temperature with diamine reagent. The high pH promotes fluorine elimination from the PVDF chains and the grafting of diamino reagent (Vitola et al. 2015) (Fig. 2).

Subsequently the pendant amino groups can be activated for enzyme immobilization in mild conditions using condensing reagent like glutaraldehyde (Fig. 3).

Polymeric membrane based on polyethersulfone (PES) is widely used membranes in ultrafiltration processes due to their high performance and low-cost profile. PES membranes have been used also in more sophisticated application such as carrier for immobilization of bioactive molecules in membrane bioreactors. For this aim effort has been done to introduce reactive

Biocatalytic Membrane Reactors with Chemically Bound Enzyme, Fig. 2 Possible mechanism of alkaline-induced DAMP grafting on PVDF

Biocatalytic Membrane Reactors with Chemically Bound Enzyme, Fig. 3 Illustration of various steps for PVDF functionalization with amino groups and subsequent enzyme attachment via cross-linking with glutaraldehyde

groups for biomolecule immobilization without affecting the overall bulk properties. Photochemical surface modification of existing PES membrane is the most popular technique for introduction of reactive groups on PES membrane. In fact PES has an intrinsic photoreactivity making possible to perform the modification in mild reaction condition. Monomer like acrylic acid has been grafted in this way on PES membrane and then activated for enzyme immobilization using 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC).

Inorganic membranes, such as alumina, titania, silica, etc., can be also used for enzymatic immobilization via covalent binding if functionalized in a suitable way. Hydroxyl groups present onto inorganic membrane surface are not able to directly coupling enzymes. Activation of hydroxyl groups can be performed by silanization reagents, such as (3-aminopropyl)triethoxysilane (APTES).

APTES exhibits terminal amino groups available for the attachment of cross-linking reagents such as glutaraldehyde. Terminal aldehydic group of glutaraldehyde reacts with the exposed amino groups of the organosilane by forming a Schiff base. Final covalent binding occurs through formation of a new Schiff base between aldehydic terminal group of glutaraldehyde and amino groups exposed from the enzymatic amino acid residues of lysine (S. Tanvir et al. 2009). Schematic reaction of an example of enzymatic covalent immobilization onto inorganic supports is illustrated in Fig. 4.

Applications of covalently immobilized membrane systems are membrane electrodes for analytical purposes, reactions of substrates whose molecular weight is low as compared to membrane molecular weight cut-off, and enzymatic conversion of macromolecules to lower molecular weight species able to permeate the supporting membrane.

²Separation and Conversion Technology, Flemish Institute of Technological Research (VITO), Mol, Belgium

Membranes are used in bioreactors as selective barriers and sometimes also as a support/carrier matrix for enzyme immobilization. Such reactors are referred to as biocatalytic membrane reactors (BMRs). The immobilization of enzymes on membranes can be of two types: (i) nonspecific immobilization or (ii) specific immobilization (Fig. 1). Nonspecific immobilization is often random and proceeds through the numerous lysine residues on

the protein. In this process, enzymatic activity is significantly decreased largely due to different orientations of the enzymes with respect to the membrane or to multiple point attachment which also renders the active site inaccessible for the substrates or sometimes results in complete denaturation of enzymes. Methods of nonspecific immobilization include adsorption, nonspecific covalent binding, entrapment, and encapsulation. Therefore, it is essential to develop methodologies for site-specific immobilization of the enzymes with the active (or binding) site directed away from the membrane. This would ensure that benefits of enzyme immobilization could be availed without compromising on their activity.

Specific immobilization or site-specific immobilization of enzymes depends a lot on the type of enzyme and support material (membranes in the case of biocatalytic membrane reactor). Depending upon the enzyme structure and characteristics, various strategies can be used to conduct site-specific immobilization (Butterfield et al. 2001). For example, if an enzyme does not contain any cysteines (or any cysteines that are required for activity), then the site-directed mutagenesis approach may be used. This approach aims at introduction of unique cysteines to enzymes. The enzymes are attached on thiol-reactive surfaces through the sulphydryl group on the side chain of the introduced cysteine, which is located on the opposite side of the protein from the active site. An example of such an enzyme is subtilisin, a protein normally devoid of cysteine (Vishwanath et al. 1998). Another approach in this field is gene fusion which is used to incorporate a peptidic affinity tag at the N- or C-terminus of the enzyme. The enzymes are then attached from this affinity tag to anti-tag antibodies on membranes. The gene fusion approach is appropriate when the N- or C-terminus of the enzyme are away from the active site. Gene fusion methods have been employed to investigate site-specifically immobilized alkaline phosphatase (AP) on functionalized membranes (Vishwanath et al. 1997). Another method considered to be of biomimetic inspiration is the posttranslational modification to incorporate a single biotin moiety on enzymes. The enzymes can be attached to membranes through a (strept)-avidin bridge.

B

Biocatalytic Membrane Reactors with Site-Specific Immobilized Enzyme, Fig. 1 (a) Random immobilization of enzymes, showing potential difficulties. (b) Site-specific immobilization of enzymes to form an

array of similarly oriented proteins, always with the active site away from the polymer surface (Butterfield et al. 2001)

This modification incorporates a biotin moiety on a specific lysine residue on the enzyme, which allows the use of an avidin spacer between the enzyme and the immobilization surface. Biotin, a vitamin, has an affinity for avidin, a protein found in egg whites, that is a remarkably strong association. An example of such an enzyme is beta galactosidase immobilization on polyethersulfone membranes (Vishwanath et al. 1995).

From the membrane point of view, some of the approaches for site-specific attachment of the enzyme include modifying the membranes by attaching functional groups such as sugar and polypeptides to which the enzymes eventually bind (Mazzei et al. 2010).

Biochemical Conversion

Yamini Satyawali, Ehiase Augustine Ehimen and Winnie Dejonghe
Separation and Conversion Technology, Flemish Institute of Technological Research (VITO), Mol, Belgium

Biochemical conversion refers to the application of biologically mediated processes to facilitate the production of a range of chemical products and power. This conversion route involves the direct use of living organisms (i.e., whole cells) or desired active protein constituents (i.e., enzymes and antibodies) extracted from living cells to aid the reformation of reactant species to desired products or the synthesis of new chemicals.

Biochemical conversion processes thus rely on biocatalytic transformation systems for achieving synthetic chemistry goals. Historically, such processes have been applied for centuries for alcohol (via fermentation) and cheese (via enzymatic degradation of milk proteins) production in different geographical regions globally using different techniques but with similar underlying conversion principles. Increased knowledge on protein structure (including protein design tools, i.e., rational design and directed evolution) and function relationships has further improved scientific understanding of biochemical conversion processes and thus has helped to advance its adaptation, implementation, and application (up to industrial scales) in recent decades.

The substrates employed for biochemical conversion schemes can be derived directly or

indirectly from biomass sources (i.e., plant and animal) as in the case of the anaerobic digestion of biomass for the production of a range of volatile fatty acids (carboxylic acids with chain lengths C_1 – C_5) and methane (CH_4) which have applications in the chemical and energy industry, respectively. Here, a multistage degradation of the complex polymers and compounds (which make up the biomass substrate) to lower molecular weight products is facilitated by a consortium of anaerobic bacteria (whole cells). The enzymatic transesterification or esterification of biologically obtained triglycerides to fatty acid methyl esters using the enzymes-lipases is another example of such bio-derived substrate for biochemical conversion. The conversion of non-biomass-derived substrates is also feasible, with the synthesis of new chemical products, obtainable via the transformation and degradation of chemical reactants with the application of biochemical conversion methods. An example is the asymmetric synthesis of chiral amines from prochiral ketones (which has a significant interest from pharmaceutical industries), i.e., 4-phenyl-2-butylamine production via the transamination of 2-propylamine and 4-phenyl-2-butanone with ω -transaminases used as the process biocatalyst. With approximately 100 different biocatalyst-mediated processes applied in the pharmaceutical, food, chemical, agricultural, and cosmetic industries, the product ranges from biochemical conversion processes range from specialist research and commodity chemicals, to food and fuel products (Wandrey et al. 2000).

With the biochemical conversion schemes highly dependent on the use of biocatalytic processes for achieving product synthesis, the major advantage with the use of this route is the high selectivity obtainable. This selectivity which can be chiral (i.e., stereoselectivity), positional (i.e., region selectivity), and functional group specific (i.e., chemo-selectivity) is highly desirable in chemical synthesis since it may offer benefits such as the none or reduced use of protecting groups, a minimization of side reactions, ease in downstream separation of products, and possible

fewer environmental issues (Johannes et al. 2006). Compared with chemical and thermochemical conversion technologies, the application of biochemical conversion processes has been highlighted to be generally more efficient (with a lower biocatalyst concentration employed compared to chemical catalysis requirements) with milder process reaction conditions (usually with temperature and pH ranges of 20–40 °C and 5–8, respectively, for most biochemical processes) as opposed to the harsher pressure, temperature, and pH operation conditions usually applied for chemical conversions. Biochemical conversion technologies also possess the advantage of being modifiable to increase selectivity, stability, and activity of the applied biocatalyst to improve the product yields of the targeted conversion process, the possibility of the biocatalyst recycling (which could aid a reduction in the process wastes and costs), and potentially having superior environmental benefits (i.e., nontoxic by-products or side reactions, non-production of process effluents, and reduced energy process inputs) compared with the use of chemical/thermochemical conversion schemes.

The main disadvantages with the use of biochemical conversion systems are its inhibition susceptibility (including substrate and product inhibition), the limiting operation ranges where biochemical conversions can be applied (since biocatalysts usually have an optimal operational pH, temperature, etc.), and the water requirements for most processes (which could potentially be disadvantageous from a downstream processing and energetics perspective).

Biocatalytic membrane reactor

A biocatalytic membrane reactor (also referred to as a biochemical membrane reactor) is a system or device that combines and utilizes the separation capabilities of membranes and the catalytic activities of whole cell or enzyme biocatalysts in one unit to facilitate the biochemical conversion of substrates into desired products and the selective removal of the products in a single process unit. The removal of the product components from the reaction site could in turn improve the conversion of the substrates by favoring the product formation reaction and is thus useful for reactions that are thermodynamically unfavorable or are product inhibited. The separation of permeable solutes can be achieved from the reaction mixture by the action of a driving force that is applied across the membrane. As a result of coupling the conversion reaction with separation, lower operating costs could therefore be achievable with this type of reactor design compared to the use of multiple reaction and product separation methods.

The complete retention of the biocatalyst within the reactor system is the most important requirement for the successful continuous operation of biocatalytic membrane reactors. Ultrafiltration membranes with a pore size distribution range (nominal molecular weight cutoff, NMWCO, of 500–100 kDa) are the most adequate for the retention of a majority of native or

modified enzymes (10–100 kDa) (Prazeres and Cabral 1994).

The biocatalyst is usually present in the reactor system in two forms: free or immobilized at the membrane surface, or inside the membrane matrix pores. If the biocatalyst (i.e., enzyme) is present in its free form, its immobilization can be achieved by confining the enzyme to one side of the membrane unit. This can be facilitated by size exclusion, electrostatic repulsion, or enlargement via chemical or physical immobilization techniques onto an intermediate support (i.e., inert proteins and gels). As for the direct immobilization of the biocatalyst onto the membrane, this can be achieved by chemical binding, physical adsorption, or electrostatic attraction.

Ideally, the products resulting from the biocatalytic process should permeate through the membrane pores either via a concentration gradient-induced diffusion or a pressure gradient-induced convection. This would in turn facilitate a continuous removal of products from the reaction media, a process which has been considered to be essential for biocatalytic membrane reactor concepts. The selection of the membrane unit to be incorporated into the reactor system must take into account the respective sizes of the enzymes, substrates, and products, as well as the chemical characteristics of the reacting species and of the membrane. Here, the solute rejection coefficient is an important membrane selection parameter for the reactors and should be zero and one for the products and the biocatalysts, respectively (Prazeres and Cabral 1994). This would allow for the product/coproduct permeation through the membrane and a complete retention of the biocatalysts inside the reaction system.

The configurations of biocatalytic membrane reactors can be categorized into two main types (Fig. 1) (Giorno and Drioli 2000):

1. The biocatalyst (i.e., whole cells, enzymes, or antibodies) are used in solution for the conversion of the substrate to the desired products in a reactor and further transported to a reaction vessel containing a selected membrane where

Biochemical Membrane Reactors, Fig. 1

Main configuration types for biocatalytic membrane reactors; (1) conversion reactor combined with a membrane unit, (2) submerged membrane reactor with the membrane functioning as a catalytic and separation unit (Adapted from Giorno and Drioli 2000)

Biochemical Membrane Reactors, Table 1 Advantages and disadvantages of biocatalytic membrane reactors (Prazeres and Cabral 1994)

Advantages	Disadvantages
Possibility of developing continuous conversion processes	Unfavorable adsorption and enzyme-poisoning issues
Improved control of reaction systems	Enzyme deactivation due to shear-related effects
Increased productivities	Concentration polarization
Contribute in a favorable shift of the reaction toward product side	Likely product/substrate inhibition at the membrane surface
Better conversion rates in product-inhibited reactions	Membrane fouling
Good product enrichment and concentration in process stream	Enzyme leakage
Facilitates control of the molecular weight of hydroxylates	
Allows the conducting of multiphase reactions without emulsification issues	
Useful refined research tool for studying enzyme mechanisms	

the biocatalysts (and unreacted substrates) can be recycled back to the conversion reactor, with the permeate selectively extracted from the reaction stream. Here, the biocatalytic membrane reactor system might consist of a conventional stirred-tank reactor combined with a membrane separation unit.

2. The biocatalyst constituents are immobilized within the membrane of the matrix. Here, the

membrane acts as a support system for the biocatalyst as well as a separation unit.

The membrane units of the membrane reactor system can comprise of membranes which have a flat sheet shape (i.e., arranged in a plate and frame module or a spiral wound module) or tubular (assembled in a tube – and – shell module) (Giorno and Drioli 2000) (Table 1).

Biochemical Processing

Yamini Satyawali¹, Ehiازه Augustine Ehimen² and Winnie Dejonghe²

¹Separation and Conversion Technology, Vlaamse Instelling voor Technologisch Onderzoek (VITO), Boeretang 200, Belgium

²Separation and Conversion Technology, Flemish Institute of Technological Research (VITO), Mol, Belgium

Biochemical processing refers to the use of biologically derived or biochemical techniques to meet the following goals: (i) to facilitate the conversion of specific substrates to products, (ii) as a process pretreatment scheme for the production of intermediates with the aim of achieving increased production yields or quicker conversion times, and (iii) to aid the recovery, recycling, or purification of a process intermediate or product.

Particularly in biochemical processes such as fermentation, the need for purification and concentration of the components is highly significant. Cell removal, whole broth clarification, downstream recovery, and purification of bioproducts from invariably dilute and often complex aqueous mixtures form an important aspect of biochemical processing. Furthermore, up to a few years, the

major amount of pharmaceuticals was produced via chemical synthesis processes. Nowadays, biotechnology productions dominate the pharmaceutical market, and membrane technology operations come to the fore due to the requirements of higher productivities.

In fact, membrane processes have been used in biochemical processing since well before the start of the modern membrane industry. Membrane technology for enzyme concentration, analysis of bacteriophages and viruses, preparation of cell- and protein-free ultrafiltrates from biological solutions, and sterile filtration has been widely used. These systems were however limited to analytical-scale processes due to limitations on the available membranes and modules. Over the last two decades, new membranes, modules, and systems have been developed specifically to meet the requirements of the biotechnology industry (Reis and Zdney 2007).

Particularly, in biochemical processes, with the technological advancements such as increased product titers of cell cultures from 1 to 3 g/L up to concentrations of 10 g/L, membrane unit operations found a stronger application throughout the production, purification, and formulation of biotechnology products. The membrane processes are applied in upstream applications including sterile filtration of fermentation media, pH control solutions, and gases. Furthermore, microfiltration may be used for turbid streams, virus filtration to protect cell cultures from introduction of viral contaminants in media, and ultrafiltration to remove, e.g., glycine, hypoxanthine, and thymidine from serum. On the other hand, in downstream processing, multiple operations are used such as sterile filtration of buffers, products and gases, and further membranes are integrated as sieving filtrations or as membrane chromatography steps. Ultrafiltration is used to concentrate and buffer exchange (diafiltration) products throughout the downstream process and is also used as the method of choice for final formulation of bulk product. Membrane chromatography can be used for purification of products and raw materials, e.g., the removal of endotoxins from raw materials, before using them in downstream processing. Membrane technology has high

potential in the field of biopharmaceutical production, and this needs to be fully exploited in the coming years (Fröhlich et al. 2012).

In addition, bioconversion processes such as production of biofuels from biomass (biorefinery concept) are also a suitable example of biochemical processing. Typical technologies that have been incorporated into the process include ion exchange resins that are being used for the detoxification of fermentation hydrolyzates, distillation in the recovery of ethanol and ethanol dehydration, and membrane separation for the removal of water from ethanol solution (Huang et al. 2008).

²Separation and Conversion Technology, Flemish Institute of Technological Research (VITO), Mol, Belgium

An important step in any biochemical processing or conversion is the recovery of the process intermediates or products of interest. This is especially important since most biochemical processes are conducted using very dilute conditions, with the desired product concentration as required which in turn varies over a wide range. The final product concentration and thus the extent of the product recovery is highly dependent on the preceding process/reaction conditions and the market costs

of the biochemical products. For example, for some organic acid fermentations, i.e., citric acid and glutamic acid, concentrations of 100 g/L or greater can be achieved (Wang 1983). Alternatively, with some more complex, specialized macromolecular products, i.e., vitamin B₁₂ and human insulin, concentrations of 1 g/L or less are usually considered to be satisfactory since these products command premium prices (Wang 1983). Applying schemes for concentrating the product in the medium from which it must be recovered is thus required and usually constitutes a significant cost. Depending on the medium/reaction dilution levels and the type of product recovery route applied, the recovery costs and in turn total process costs could be quite high. The extent of product concentration and purification achieved by the applied recovery process has a direct implication on the product costs and the profitability of the process, with an almost linear relationship demonstrated between the selling price of biochemical products and the concentrations of the products (Belfort 1989).

The product purification and its concentration are thus the two main considerations and form the basis guiding the selection of suitable downstream recovery schemes for biochemical processes. Ideal recovery systems should therefore strive for the reduction of the volumes of the medium, and a purification of the desired products while concentrating.

For the recovery of products from the dilute reaction medium, in addition to the extent of the dilution of the desired product, the medium constitution and complexity is also a factor which must be considered. This is because different classes of materials are usually present in the biochemical process streams (i.e., suspended and colloidal solids, microorganisms and cell debris, macromolecular solutes and microsolute) (Michaels and Matson 1985). The different size ranges exhibited by these medium components therefore pose a significant separation issue which must be carefully considered before a recovery scheme is applied. Furthermore, the fact that some biochemical products are normally susceptible to degradation due to changes in the temperature, ionic strength, pH, shear rate, and solvent conditions adds to the need for careful planning of the product recovery route (Michaels and Matson 1985).

Biochemical Recovery, Table 1 Conventional and membrane bioseparation technologies for product recovery (Michaels and Matson 1985)

Unit operation	Conventional process or equipment	Membrane process applicable
Cell harvesting	Rotary vacuum drum	Crossflow microfiltration (MF)
	Filtration	Ultrafiltration (UF)
	Centrifugation	
Whole broth clarification	Centrifugation	Crossflow MF, UF
Protein concentration/purification	Electrolyte/solvent precipitation	UF
	Affinity column chromatography	Diafiltration
		Membrane modulated protein precipitation
		UF affinity purification
		Membrane-bound affinity ligand chromatography
Desalting	Size-exclusion chromatography	Electrodialysis
Microsolute concentration	Vacuum evaporation	Reverse osmosis
		Pervaporation
		Membrane distillation
Acid/base recovery	Chemical treatment	Bipolar electrodialysis
	Ion exchange	
Solvent extraction	Podbielniak extraction	Membrane contactor solvent extraction

Different approaches can be applied to achieve an optimized recovery of the biochemical products, and there is no universal optimized recovery route applicable to every process; instead, the recovery options are usually selected to particularly suit the individual process and product case under consideration. The selected recovery process is also quite important especially since the recovery costs for some products have been reported to be considerably greater than the bioprocessing costs for the production of the product.

The selection of a suitable, industrial scalable recovery process is an important step in the downstream processing of products. The use of recovery methods such as adsorption, centrifugation, electrophoresis, chromatographic, solvent extraction, and membrane processes has been largely applied for biochemical processes. The different available recovery technologies can be selected on the basis of the manipulation of specific molecular characteristics of the desired product such as its molecular size, diffusivity, ionic charge, vapor temperature and pressure, solubility, surface activity, and its density.

The application of membrane techniques and its use for biochemical product recovery will be the main emphasis of this section.

Table 1 provides a summary of common biochemical product recovery unit operations and examples of conventional separation techniques usually applied for the desired product recovery. A comparison with the membrane processes which can also be applied for such processes are also presented in Table 1.

The selected biochemical recovery scheme, especially with the use of membrane techniques, can either be carried out as a downstream process (where the biochemical process is run batchwise) or integrated with the biochemical reaction, i.e., the use of in situ product recovery (or coproduct) methods. With the latter, the biochemical processing can be conducted continuously with the process reactants, and biocatalysts returned back or retained in the reactor. The use of such a method, in addition to the concentration and recovery of the desired product, might also help improve the biochemical process to favor the product formation (i.e., since its continuous removal will favor a shift of the reaction equilibrium toward product production).

Biocidal and Self-Polishing Surfaces

Li-Ping Zhu

MOE Key Laboratory of Macromolecular Synthesis and Functionalization, Department of Polymer Science and Engineering, Zhejiang University, Hangzhou, Zhejiang, China

Biocidal and self-polishing surface is a surface that features the capability of preventing the settlement and colonization of biofouling microorganisms through biocide release and surface smoothing via a gradual hydrolysis of the paint film in wet environments. Biofouling is defined as the undesirable adhesion, adsorption, accumulation of microorganisms, plants, animals, proteins, and cells, etc., on a wetted surface, and it is of high concern in shipping industry. Biofouling on vessels increases hull roughness and hydrodynamic drag, which leads to a decrease in vessel performance and an increase in fuel consumption (Kirschner and Brennan 2012). Furthermore, hull maintenance of extensively fouled ships is costly as it is difficult to remove the biofilm. It is estimated that the fuel consumption can increase more than 40 % for a heavily fouled ship. Governments and industries around the world spend more than US\$ 5.7 billion annually to prevent and control marine biofouling (Yebra et al. 2004). A biocidal surface is usually designed by impregnation of coating with biocides which are released to kill the near microbes and resist biofouling. However, the release of heavy metal-based biocides from antifouling paint films often leads to an adverse impact on the marine environment and

more specifically on nontargeted marine livings due to their high persistence and toxicity. In recent years, some biocidal surfaces containing antimicrobial groups have been designed to kill and/or release the contacted microbes without leaching out biocides. These nontoxic biocidal surfaces have been developed and used in ship antifouling to meet the restrictive legislations (Siedenbiedel and Tiller 2012).

A self-polishing surface means the surface is able to keep smooth and clean through continuous polishing from the hydrolysis and dissolution of paint top layer in moist environment and hydrodynamic friction. The term “self-polishing” has been introduced with the development of tributyltin self-polishing copolymer (TBT-SPC)-based antifouling paints (Cavas and Alyuruk 2013). The first use of the term in the marine paints industry is directly related with the working mechanism of TBT-SPC paints. The possible use of TBT acrylate esters in antifouling paints was first suggested by Montermoso and co-workers in 1958. TBT-SPC technology was then patented by Milne and Hails in 1974. The general working mechanism of commercially used TBT-SPC depends on the hydrolysis of the ester bond between the TBT moiety and the carboxyl group of the polymer backbone. TBT acts as a broad-spectrum biocide and can be incorporated into antifouling paints to inhibit fouling on a ship hull up to 5 years. The TBT-SPC paints were so successful that they have been applied in about 70 % of commercial ship. However, the release of toxic TBT into seawater has brought detrimental effects on nontargeted marine organisms and environments. As a result, many governments as well as the International Maritime Organization have restricted, even banned, the use of organotins in antifouling paints. In recent years, many researchers and companies have been devoting many efforts to explore non-tin self-polishing paints as a replacement of TBT-based paints (Lejars et al. 2012).

Biocidal Graphene Oxide Nanosheets

Francois Perreault

School of Sustainable Engineering and the Built Environment, Arizona State University, Tempe, AZ, USA

Biocidal graphene oxide nanosheets are used to provide antimicrobial properties to surfaces. Graphene is a two-dimensional nanomaterial composed of a single atomic layer of sp^2 -bonded carbon atoms. This material came into prominence in 2010 by the awarding of the Nobel Prize in Physics to Andre Geim and Konstantin Novoselov for their research on the properties of graphene. Graphene exhibits excellent electrical, mechanical, optical, and thermal properties that allow its widespread application in photovoltaic devices, transistors, sensors, and electronic visual displays. Graphene possesses the highest theoretical specific surface area ($2630 \text{ m}^2 \text{ g}^{-1}$) due to its two-dimensional, one-atom-thick structure and thus constitutes an excellent candidate for sorbent material used in water decontamination and gas separation (Zhu et al. 2010). Graphene also possesses good antimicrobial activity and has found several applications for the development of antimicrobial surface coating. Graphene and its oxidized form, graphene oxide, possess a broad-spectrum antimicrobial effect, being effective against gram-positive bacteria, gram-negative bacteria, and

fungi. Cell inactivation by graphene nanomaterials occurs by a combination of cell entrapment, membrane disruption, and the generation of reactive oxygen species, leading to membrane oxidative stress. For all these mechanisms, direct contact between bacterial cells and graphene sheets is required. The antimicrobial potential of graphene nanomaterials is dependent on the physicochemical properties of the material such as sheet size, conductivity, and degree of functionalization.

The biocidal potential of graphene and graphene oxide sheets has been successfully used to impart antimicrobial properties to membranes. For water separation membranes, graphene oxide is usually preferred over reduced graphene due to the more hydrophilic nature of this material. The incorporation of graphene oxide sheets into a membrane for antimicrobial properties may therefore also increase the hydrophilicity of the membrane surface. Graphene oxide sheets can be incorporated in membranes by including the nanomaterials in the polymer solution during fabrication or by post-fabrication surface functionalization. When included in the polymer solution, graphene oxide also contributes to the overall mechanical strength of the membrane and influences its porosity and transport properties (Yu et al. 2013). Since graphene oxide sheets require direct contact for cell inactivation, only the graphene oxide sheets on the membrane surface contribute to the membrane antimicrobial activity. Graphene oxide sheets deeper in the membrane structure do not participate in bacterial inactivation. In order to reduce the amount of material needed to impart antimicrobial properties to a membrane, graphene oxide sheets can be concentrated on the membrane surface via surface functionalization methods. These may involve direct binding of graphene oxide sheets to the membrane using the functional groups of graphene oxide (Perreault et al. 2014), electrostatic interaction between the membrane surface and functionalized graphene oxide (Choi et al. 2013), or the incorporation of the nanomaterial in a polymer composite that is deposited on the membrane surface (Musico et al. 2014). Due to the hydrophilic properties of graphene oxide and the low slip length of water on graphene sheets, the addition of a graphene oxide layer on a membrane surface

for antimicrobial properties do not affect water transport properties.

Biodegradable membranes consist of thin-film-like structures usually applied as separating selective

barriers and support devices. These structures are generally composed of biodegradable polymers, complemented with additives, such as plasticizers, emulsifiers, and cross-linking agents. To be considered biodegradable, all membrane components must be degraded by the action of microorganisms and converted into water, carbon dioxide and/or methane, and new cell biomass.

The wide range of polymers used in the development of biodegradable membranes enables the production of structures with quite diverse properties, finding applications in different areas. It is interesting to note that some of them, beyond being biodegradable, are also biocompatible and/or edible, extending their use to the fields of biomedicine and edible coatings for food products.

Biodegradable polymers obtained by chemical synthesis have been used, for example, in food packaging materials (Siracusa et al. 2008) and medical applications (e.g., fracture fixation, dental orthopedic implants, artificial skin, suture anchors, drug delivery) (Yen et al. 2009; Armentano et al. 2010; Bettahalli et al. 2011). They have also been applied for separation of organic mixtures by pervaporation (Zereshki et al. 2010, 2011).

They include the following:

- (i) Polyglycolic acid (PGA), an aliphatic–aromatic copolymer, which combines the excellent material properties of aromatic polyethylene terephthalate and the biodegradability of aliphatic polyesters. It is produced by a polycondensation reaction of glycol and aliphatic dicarboxylic acids, which may be obtained from renewable resources.
- (ii) Polylactic acid (PLA), a thermoplastic aliphatic polyester obtained from polymerization of the lactic acid monomer produced by microbial fermentation.
- (iii) Polycaprolactone (PCL), a thermoplastic polymer obtained by chemical synthesis using nonrenewable resources (petrochemical derivatives).

Among the biodegradable polymers produced by microbial fermentation, polysaccharides (e.g.,

pullulan, hyaluronan, gellan, GalactoPol, curdlan, bacterial alginate, bacterial cellulose) (Freitas et al. 2011) and polyesters (e.g., polyhydroxyalkanoates) have been applied in films and edible coatings (e.g., pullulan, gellan) (Nieto 2009; Alves et al. 2011). Both microbial polysaccharides and polyesters show a wide range of properties that may be tuned by manipulating the bioreaction conditions. Polyhydroxyalkanoates show a wide range of applications, such as in industry (e.g., packaging, waterproof paperboard), medicine (e.g., bone plates, osteosynthetic materials, surgical sutures, and dressing materials for surgery), and agriculture (e.g., mulch films) (Philip et al. 2007).

The polymers recovered from natural products generally used to produce biodegradable membranes include polysaccharides (e.g., starch, cellulose, pectin, alginate, carrageenan, chitosan) and proteins (e.g., gelatin/collagen, soy protein, gluten). These polymers are widely used to develop edible coatings for food products and biodegradable films intended for food packaging (Nieto 2009). Chitosan, alginate, and collagen are also referred to be applied in tissue engineering (Eisenbarth 2007).

Polysaccharide-based membranes, such as chitosan and sodium alginate, have received much attention for solvent dehydration by pervaporation, due to their good film-forming properties, chemical resistance, and high permselectivity for water (Chapman et al. 2008; Yu et al. 2006).

Portugal

Biodegradable organic matter is organic material, plant, and animal matter with origin in living organisms, which can be converted by the action

Biodegradable Organic Matter, Fig. 1 Biodegradable polymers

of microorganisms to water, carbon dioxide, and/or methane and biomass.

Organic materials can be used to obtain biodegradable polymers which are classified according to the method of production or their source (Fig. 1):

- Polymers directly extracted or removed from biomass such as polysaccharides and proteins
- Polymers produced by classical chemical synthesis starting from renewable bio-based monomers such as polylactic acid (PLA)
- Polymers produced by microorganisms or genetically modified bacteria such as polyhydroxyalkanoates, bacterial cellulose, xanthan, and pullulan (Mensitier et al. 2011)

Polysaccharides are the most abundant macromolecules in the biosphere. These complex carbohydrates constituted of monosaccharides joined together by glycosidic bonds are often one of the

main structural elements of plant and animal exoskeleton (e.g., cellulose, carrageenan, chitin) or have a key role in the plant energy storage (e.g., starch).

Cellulose and starch are of prime interest as biopolymers because of their availability and rather low cost. A variety of polysaccharides and their derivatives, besides starch and cellulose derivatives, have been used as biodegradable membrane-forming matrixes, including alginate, pectin, carrageenan, chitin, and various gums.

Several protein sources have been proposed for the preparation of biopolymers, in particular, cereal proteins which are available in large amounts as by-products arising from agricultural and biofuel processing activities such as ethanol production. These protein-rich products include spent grain from the brewing and distilling industries, cereal bran streams from milling, and protein residues from starch extraction activities (Mensitier et al. 2011).

Microbial biopolymers are naturally synthesized by microorganisms with different functions in the microbial cell, including intracellular carbon or energy storage reserves (e.g., glycogen, polyesters), structural cell wall components (e.g., chitin, β -glucans), and extracellular biopolymers (e.g., exopolysaccharides), often secreted as protective mechanisms in response to environmental conditions (Rehm 2010).

A wide range of agro-food and industrial wastes/by-products have been proposed as alternative substrates for the production of microbial biopolymers, including molasses, cheese whey, palm date syrup, olive mill wastewater (OMW), glycerol by-product from the biodiesel industry, corn-steep liquor, spent malt grains, apple and grape pomaces, citrus peels, peach pulp, used oils, and several acid-hydrolysate wastes (e.g., melon, watermelon, cucumber, tomato, rice), among others (Freitas et al. 2011; Verlinden et al. 2011).

The microbial biopolymers produced include polysaccharides, polyamides, polyesters, and polyanhydrides. Depending on their composition and molecular weight, they have properties ranging from rheology modifiers to bioplastics, which makes them useful in many industrial applications (e.g., agro-food, cosmetics, pharmaceutical, textile) (Rehm 2010).

Biodegradable Polymer for Membranes

Membranes made of biodegradable polymers are stable and durable for a specific period of time related to their intended purpose or use in a particular application; after that they break down to result in natural by-products such as gases (CO_2 , N_2), water, biological materials, and inorganic salts.

Biodegradable polymers are naturally and biologically derived or synthetically made and consist of ester, amide, and ether functional groups or bonds.

Naturally and biologically derived polymers are found in nature or created by living organisms. They include *polysaccharides*, like starches found in potatoes or wood, and *proteins*, such as animal-based whey or plant-derived gluten. Polysaccharides consist of glycosidic bonds, between a saccharide and an alcohol; proteins of peptide bonds or amide functional groups between amino acids.

Synthetic materials are man-made. The most important group of synthetic biodegradable polymers is *polyesters* that include *polyhydroxybutyrate* and *polylactic acid*. They can be synthesized in a number of ways including direct condensation of alcohols and acids, ring opening polymerizations (ROP), and metal-catalyzed polymerization reactions. A wide variety of starting materials can be used to synthesize

polyesters, like cyclic dimeric glycolic or lactic acid to form α -hydroxy acids which then polymerize into *poly(α -esters)*, *poly(β -esters)*, and *poly(γ -esters)*. Other synthetic biodegradable polymers are *polyanhydride* and *poly(ester amide)s*, made by condensation, dehydrochlorination, dehydrative coupling, and ROP, and *polyurethanes*, typically synthesized using a diisocyanate, a diol, and a polymer chain extender.

Biopolyesters are produced by both living organisms and synthetic processes. These metal-free processes involve the use of bacterial or enzymatic catalysis, with the benefit of generally regioselective and stereospecific reactions, but with the drawbacks of the high cost of bacteria and enzymes, long reaction times, and products of low molecular weight. Examples of biopolyesters are *poly(glycolic) acid* and *polyhydroxyalkanoates (PHA)* (Zhang et al. 2014).

Membranes made of biodegradable polymers have numerous applications in a variety of fields including medicine, agriculture, and packaging. In the biomedical field, they are of significant interest in applications such as tissue engineering and drug delivery. For these applications biodegradable polymers must answer to specific requirements: they must be nontoxic, capable of maintaining good mechanical integrity until degraded, and capable of controlled rates of degradation. Their products of degradation require also low or negligible toxicity in terms of both local tissue response and systemic immune response.

Biodegradability in tissue engineering is often an essential factor since scaffolds should preferably be absorbed by the surrounding tissues without the necessity of a surgical removal. The rate at which degradation occurs has to coincide as much as possible with the rate of tissue formation: this means that while cells are building their own natural matrix structure around themselves, the scaffold should be able to provide structural integrity within the body and eventually to break down without evoking a foreign body response and leaving the newly formed tissue. They should be

eliminated from the body via natural metabolic pathways. If they are of natural origin, they should be further incorporated in the new forming tissue matrix (Williams 2014). Commonly used natural biodegradable polymers are different proteic derivatives of the extracellular matrix, such as *collagen*, *elastin*, *keratin*, and *fibrin*, and polysaccharidic materials, like *chitosan* and *glycosaminoglycans (GAGs)*. Although they have all proved suitable in terms of cell compatibility, some issues with potential immunogenicity still remains. Among the synthetic materials, *polyurethanes* and *poly(ester amide)s* were initially used for their biocompatibility, durability, and resilience and are only more recently being investigated for their biodegradability. A commonly used synthetic polymer is *polylactic acid (PLA)*, a polyester which degrades within the human body to form lactic acid, a naturally occurring chemical which is easily removed from the body. Similar materials are *polyglycolic acid (PGA)* and *polycaprolactone (PCL)*: their degradation mechanism is similar to that of PLA, but they exhibit, respectively, a faster and a slower rate of degradation compared to PLA. *Polyglycolide*, *polylactide*, *polyhydroxybutyrate*, *chitosan*, *hyaluronic acid*, and *hydrogels* are used in orthopedic applications, such as bone and joint replacement; *poly(2-hydroxyethyl-methacrylate)*, *polyethylene glycol*, *chitosan*, and *hyaluronic acid* are extensively used in the repair of cartilage, ligaments, and tendons (Chiono et al. 2014; Jagur-Grodzinski 2006).

Biodegradable polymeric membranes are of great interest and benefit as drug delivery systems and carriers, where it is critical to target and slowly release the payload drug over time and into a specific site of the body. The polymer slowly degrades into nontoxic and naturally metabolized smaller fragments releasing in the meantime the drug in a controlled fashion. Biodegradable polymers for this purpose must be capable to be formulated for prolonged release of pharmaceutically active compounds. Encapsulating the therapeutic in a polymer and adding targeting agents further decreases the toxicity of

the drug to healthy cells. *Polyanhydrides* are very attractive in drug delivery because they only degrade from the surface and so are able to release the payload drug at a constant rate. *PLA*, *poly(lactic-co-glycolic) acid (PLGA)*, and *PCL* have been used to carry anticancer drugs.

In addition to medicine, biodegradable polymers are often used to reduce the volume of waste in packaging materials derived from petrochemicals. One of the most commonly used biodegradable polymers for packaging purposes is *PLA*, used for a variety of films, such as wrappings, shopping bags, or trash bags, as well as containers, including bottles and cups. Since 2002, *PLA* has been approved by the Food and Drug Administration (FDA) as a safe material to use in all food packaging.

The breakdown of these polymers depends on a variety of factors including the polymer properties and the environment in which they are. Complete *biodegradation* occurs when there are no oligomers or monomers left. Polymer properties that influence degradation are bond type, molecular weight, chain branching, cross-linking, copolymers, crystallinity, hydrophobicity, and solubility. Factors of the surrounding environment, either the atmosphere or the body, include pH, temperature, the presence and concentrations of microorganisms or enzymes, and amount of water. Biodegradable polymers with extremely strong carbon backbones are difficult to break, so degradation often starts from the end groups. Biodegradable polymers with minimal chain branching and cross-linking and with low crystallinity and degree of polymerization often decrease the number of end groups per unit weight but increase their surface area and an easy access for reaction with the degradation initiator. Hydrophobic polymers cannot easily get in contact with water soluble enzymes decreasing their enzyme interaction and degradation. There are two primary mechanisms through which biodegradation can occur. One is through physical decomposition through reactions such as hydrolysis and photodegradation, which can lead to partial or complete degradation. The second mechanistic

route is through biological processes which can be further broken down into aerobic and anaerobic processes. Microorganisms and enzymes that have the ability to break down natural polymers into even simpler units act through oxidation or hydrolysis reactions. Examples of key enzymes include proteases, esterases, glycosidases, and manganese peroxidases.

Biodegradation is the process by which microorganisms (bacteria, fungi, algae) change the chemical structure of a material into naturally occurring metabolic products, ultimately resulting in its conversion into water, carbon dioxide and/or methane, and new cell biomass (Muller 2005). The biodegradation of polymeric materials starts with their depolymerization to generate lower molecular weight intermediates that the microbial cells can then assimilate. The general mechanism of the biodegradation process includes three phases: (1) secretion of extracellular enzymes by the microorganisms; (2) generation of short intermediates by the action of the secreted enzymes; and

(3) conversion of the intermediates into metabolic products (Fig. 1). Water soluble polymers, such as the natural polysaccharides xanthan, alginate, and pectin, are usually more easily degraded, while water insoluble polymers (e.g., polyesters) are more difficult to degrade because the process is heterogeneous. Abiotic processes, such as chemical degradation, thermal hydrolysis, or photodegradation, coexist with the biotic process and often directly induce it by making the materials more easily accessible to the microorganisms. Hence, environmental conditions (e.g., pH, temperature, moisture, salinity, presence/absence of oxygen, nutrient supply) are important factors that influence both the materials themselves and the microbial activity. The complexity of the materials, namely, the structure and composition (single polymer or polymer blends), the presence of additives (e.g., plasticizers), morphology, and crystallinity, are also key issues that directly influence their accessibility to the microbial enzymes.

The standardized methods for testing the biodegradability of polymeric materials are based on previously developed methods for low-molecular weight substances. However, they have been modified to consider their higher complexity. Different biodegradability tests can be performed, under both controlled laboratory conditions and also natural environmental conditions. In the laboratory tests, defined environments are created using one of two approaches: (1) inoculation of

Biodegradation, Fig. 1 General mechanism of the biodegradation process: (1) secretion of extracellular enzymes by the microorganisms, (2) generation of short

intermediates by the action of the secreted enzymes, and (3) conversion of the intermediates into metabolic products

 tests

B

synthetic media with individual microorganisms especially selected for a given polymer or with a mixed microbial culture originating, for example, from a wastewater treatment plant or (2) use of complex materials collected from the environment (e.g., water, soil, compost) as the matrix for the tests (Fig. 2).

Some of the standard testing methods include (Shah et al. 2008):

- Visual observations: macroscopic changes, such as roughening of the surface, formation of hole or cracks, changes in color, etc., can be used as a first indication of microbial attack, while more sophisticated observations using, for example, scanning electron microscopy (SEM) or atomic force microscopy (AFM) can be made to obtain more information about the degradation mechanism.
- Weight loss measurements: determination of residual material after being exposed to the biodegradation conditions.
- Changes in mechanical properties and molar mass: properties, such as tensile strength, can be used as indicators of degradation since they are related with the polymer's molar mass.
- CO₂ evolution or O₂ consumption: under aerobic conditions, the microorganisms use O₂ for carbon oxidation, generating CO₂ as one of the major metabolic end product. Hence, CO₂ evolution or O₂ consumption are good indicators of polymer degradation.
- Radio labeling: materials containing a randomly distributed ¹⁴C marker can be exposed

to the microbial environment and the amount of ¹⁴C generated is estimated. It is a high precision test, but labeled materials are not always available and are expensive.

- Clear-zone formation: the polymer is placed in agar plates as very fine particles and inoculated with the microbial culture, being the formation of a clear halo the indication of depolymerization.

 tor; Electrochemical membrane bioreactor; Mem-
 brane bioelectrochemical reactor

Introduction

Bioelectrochemical MBR is a novel and effective integration of membrane bioreactor process and microbial fuel cell technology, which can recover energy from wastewater and simultaneously harvest clean water for reuse (Wang et al. 2011, 2013a, b; Huang et al. 2014). As shown in Fig. 1, a typical bioelectrochemical MBR consists of an anode chamber (or anaerobic tank) and a cathode chamber (or membrane tank). In the anode chamber, fuel (e.g., organic matter in the influent wastewater) is oxidized by exoelectrogenic bacteria, generating CO_2 , protons, and electrons. Electrons are then transferred to the cathode chamber (or membrane tank) through an external electric circuit, while protons are transferred to the cathode chamber through the separators (e.g., membranes). Electrons and protons are finally consumed on the surface of cathodes to finish the reduction reaction (e.g., oxygen reduction reaction). In these devices, membrane modules are placed in the cathode chamber to enable a sound solid-liquid separation.

Separators with a high conductivity of protons and a low substrate diffusion coefficient are welcome in bioelectrochemical MBRs in order to achieve a selective mass transfer between anode

and cathode chambers (Fig. 1a). Proton exchange membrane (PEM) and anion exchange membrane (AEM) are initially utilized in bioelectrochemical MBRs because these membranes are designed to conduct protons and anions while being impermeable to other reactants (e.g., O_2). Alternatively, substitutes, such as microfiltration membrane, nylon meshes, and perforated plates (Wang et al. 2012), have been also used in bioelectrochemical MBR to separate anode and cathode chambers regarding the construction expenditure (Fig. 1b). As a consequence, coulombic efficiency can be substantially decreased due to unwanted substrate diffusion.

In bioelectrochemical MBRs, anodes are always made of carbon cloth, carbon brush, and carbon paper. The high specific surface area ($100\text{--}2,000\text{ m}^2/\text{g}$) of these materials is conducive for habitation of exoelectrogenic bacteria. Activated carbon can be also used as the anode material, especially in the application of wastewater treatment. Cathodes can be independent or combined with membrane modules. For example, stainless steel mesh has been introduced to constructed cathodes, and the dynamic membrane formed on the cathode subsequently enables the filtration process (Wang et al. 2011, 2013b). Composite cathodes make the reactor more compact,

Bioelectrochemical MBR, Fig. 1 Schematic representation of bioelectrochemical MBRs

which simultaneously alleviates membrane fouling (Liu et al. 2013). Electrochemical MBRs have been also developed by using external power to replace the generated electricity of MFC.

Biofuel

Diego Luna

Department of Organic Chemistry, University of Cordoba, Cordoba, Spain

In biofuel production by lipases, membranes are innovative devices used for different tasks. In this respect, they are applied as membrane-immobilized lipases to get the repeated use of expensive biocatalysts in biodiesel fabrication. In this way, the enzyme cost which is being currently the main obstacle for its use in biodiesel production can be overcome by lipase immobilization with the aim of reducing the production cost by reusing the enzymes. Consequently, many research works are currently developed to get efficient, robust, and cost effective membranes able to obtain immobilization of lipases in biodiesel production.

On the other hand, in the production of biodiesel, separation and purification of biodiesel is a critical technology. Conventional technologies used for biodiesel separation, such as gravity settling, decantation, filtration and biodiesel purification by water washing, acid washing, and absorbents have proven to be inefficient. In this respect, membrane reactors are being developed to produce biodiesel from several oils with methanol via enzymatic catalysis as well as by acid- and base-catalysis. Thus, membrane reactors which exhibit intrinsic characteristics of efficiency, operational simplicity and flexibility, relatively high selectivity and permeability, low energy requirements, good stability under a wide spectrum of operating conditions, and easy control have been confirmed in a numerous variety of applications and operations, such as molecular separations, fractionations, concentrations, and purifications within a wide environmental

compatibility. In this respect, novel two-phase membrane reactors seems to be particularly useful in removing unreacted oil from the fatty acid methyl ester (FAME) product yielding a high purity biodiesel. Some research could also be conducted on technologies for biodiesel production by utilizing membrane reactors to handle waste oil in biodiesel production.

Glycerol also causes strong inhibition in the enzymatic methanolysis of triglycerides; therefore glycerol removal by dialysis is carried out using flat sheet membrane modules. Thus, membrane filter devices are useful tools for obtain cleaning of glycerol in biodiesel production. Membrane separation seems to be the most suitable methodology for this purpose. Consequently, the involvement of membrane reactor and separative membrane shows great promise for the separation and purification of biodiesel. Membrane technology are currently being explored and exploited to overcome the difficulties usually encountered in the separation and purification of biodiesel. In this respect, both conventional and most recent membrane technologies used in refining biodiesel are being studied (Atadashi et al. 2011).

Biofuel Production by Membrane Operations

Lan Ying Jiang

School of Metallurgy and Environment, Central South University, Changsha, China

In integrated membrane separation for biofuel production, the most essential unit is the separation of product from the raw material mixtures. The membranes are directly combined with the chemical and biochemical conversions to improve

the productivity, biomass conversion efficacy, etc. The significance of these procedures is more than recovery and purification. By in situ removal of one of more products in some cases, they can displace the chemical reaction equilibriums or relieve the toxic effects constraining the conversion. With this feature, the system is named as biofuel production by membrane operations or membrane reactor for biofuel production. The membranes incorporated can be passive ones that only carry out separation of inhibitory product or active ones that conduct catalysis of reactions and separation simultaneously.

In bioalcohol production through biochemical conversion, the free cell continuous fermentation eliminates downtime, and cell immobilization fermentation increases cell concentration (Quresh and Ezeji 2008). However, the cell washout occurs at high dilution rate in the former. As for the latter, the limitation on substrate supply and toxic product diffusion inactivates a large amount of microbes in the latter. It is difficult for the cells located at the bottom of the biofilm to get enough carbon sources for survival, and the products and other metabolites that have inhibitory effect on the viability of microorganisms encounter great resistance in diffusing away from the cell surroundings. As a solution to these problems reducing the productivity, cell recycle membrane system, which can be called as membrane bioreactor, was developed (Quresh and Ezeji 2008).

The micro-sized cells suspended in broth are rejected by the membrane and recycled back to the reactor as retentate. Figure 1 is the schematic of the cell recycle membrane system. As a result, their concentration can be maintained. The solvents containing the products, on the contrary, pass through the membrane. If the membranes used have selectivity toward the target product, the whole production process will be further improved in economy, as the system is simplified and volume of liquid stream to be treated is reduced.

The bioreactor coupling fermentation and membrane separation has been applied in biobutanol and bioethanol productions. In the acetone/butanol fermentation using *Clostridium acetobutylicum*, the function of microbes is

Biofuel Production by Membrane Operations,

Fig. 1 Schematic of cell recycle membrane system

Separation 1: microfiltration to retain microbial cells.
 Separation 2: membranes that enrich organic component (e.g. product alcohol) at permeate side.

B

strongly inhibited by butanol, but acetone has no such toxic effect. Therefore, the purpose to couple the membrane separation is the removal of butanol. The productivity of a fermentation integrating pervaporation to remove butanol from the cultivation medium is up to 65–70 % over the one obtained without membrane separation, and the rate of substrate consumption becomes three times faster. That on-site removal of ethanol by PDMS membrane maintains the ethanol concentration and has also been proved.

Biomass thermochemical conversion technologies such as pyrolysis and gasification are not the most important options at present (Demirbas 2009). As for biogas by anaerobic digestion, gaseous metabolites can be easily taken out by stripping. Membrane separation is more often introduced into reforming steps that generate new products or adjust composition. The steam reforming of methane (CH_4) is an important way to produce syngas and supply hydrogen (H_2) used in fuel cell (Demirbas 2009). It involves two reversible reactions: reforming and water gas shift. The first is endothermic and limited by thermodynamic equilibrium. Therefore, high temperatures are used, making it slow to start up and requiring costly refractory materials. The membrane-based separation proves a cost-effective way requiring less severe operation

conditions. Productivity and conversion could be adjusted by catalyst-embedded membranes which intensify the contact between reactant and catalyst. Bernardo et al. explored CO Serox using catalytic zeolite (Pt/Na-Y) membranes in a continuous flow membrane reactor (Bernardo et al. 2008). Depending on the operating conditions, the catalytic membranes effectively reduced the CO content in H_2 from 10,000 to 10–50 ppm.

Similar to gas reforming mentioned above, transesterification encounters the limit of equilibrium conversion. FAME or glycerol as product should be removed during the reaction in order to shift the equilibrium to the product side. One of the mechanisms used for biodiesel production by membrane reactor is proposed by Dube et al. (2007). The immiscibility of oil and alcohol as well as involvement of various surface forces lead to the formation of an emulsion containing oil droplets suspended in methanol. The transesterification occurs at the surface of the oil droplets. The oil droplets could not pass through the pores of the membrane, whereas the biodiesel product will pass through the membrane pores along with the methanol, glycerol, and catalyst. As a result, the reaction equilibrium is shifted to the product side. Increases in temperature, catalyst concentration, and feedstock flow rate can increase the conversion rate.

Biofuel Separation by Membranes

Lan Ying Jiang

School of Metallurgy and Environment, Central South University, Changsha, China

Introduction

The purity of biofuels in forms of gas and liquid generated in biorefinery must meet the in-service requirements (Huang et al. 2008). Several types of membranes have been used for bioalcohols' separation. Pervaporation is molecular-level liquid–liquid separation based on the solution–diffusion mechanism. The polymeric membranes used in pervaporation are essentially dense and inorganic membranes molecularly porous (Jiang and Zhu 2013). The hydrophobic pervaporation recovers the organics from fermentation solution. Polymers such as polydimethylsiloxane (PDMS), ethylene–propylene–diene monomer (EPDM), and polyether block amide (PEBA) exhibit favorable sorption toward organic molecules due to their nonpolar functional groups and minimum diffusion discrimination. Vacuum membrane distillation (VMD) for recovery of bioalcohols uses porous membrane, and the separation is based on vapor–liquid equilibrium and Knudsen/Poiseuille flow (viscous). In comparison with pervaporation using dense membrane, VMD has higher flux but slightly lower separation factor (Urtiaga

et al. 2001). VMD is liable to wetting by alcohols and fouling by microorganisms. Yet another type of membrane is solid (i.e., propylene)–liquid (i.e., oleyl alcohol) combining extraction and pervaporation. It might also be called as membrane contactor. The process exhibited separation of 180 for butanol/water; however, the liquid portion is very unstable. Dehydration by pervaporation is for removing water in the recovered stream so that the fuel specifications could be met. It is a much easier task to achieve high separation factor in dehydration as the diffusion of water molecules is in nature faster than organics. The composite membranes using poly(vinyl alcohol) (PVA) have been commercialized.

In biodiesel production, the removal of glycerol as by-product to fatty acid alkyl esters (FAAE) is very critical. One of the separation approaches uses porous membrane (e.g., MF) (Wang et al. 2009). The immiscibility of glycerol, biodiesel, and soap added lead to the formation of reversed micelle binding glycerol at the hydrophilic site. The micelle is larger than biodiesel molecular and thus retained by the membrane. Membrane separation based on the catalytic pervaporation membrane is investigated in biodiesel production procedure (Guerreiro et al. 2006). Glycerol and methanol are able to form hydrogen bonds with the OH groups in the polymeric membrane and are continuously removed from the products during the reaction.

There exist several approaches for biogas production; they are gasification, pyrolysis, and aerobic digestion. Whichever approach, it is necessary to remove hydrogen sulfide (H_2S), ammonia (NH_3), and siloxane presenting potential damage (e.g., corrosion, erosion, fouling) to devices used in follow-up conversion and pollution to environment. Membrane made of rubbery PDMS has been employed to remove the condensable siloxane (Abatzoglou et al. 2006). In H_2 or CH_4 separation from the other bulk components (mainly CO_2) for various purity requirements, either membranes of molecular sieving or reverse selective membranes relying more on sorption selection, depending on the feed composition, are used (Shao et al. 2009).

The transmembrane flux and separation factor are the key parameters related to the economics of

the process using membrane separation (Vane 2005). For pervaporation, for example, only the permeated components actually undergo liquid–vapor phase change. Therefore higher separation factor means higher energy efficiency. Inorganic membranes generally have better separation performance than polymeric membranes in both hydrophilic and hydrophobic pervaporation. The first large-scale pervaporation plant using tubular-type module of zeolite NaA membrane for dehydration was reported in Japan. In gas separation, to prevent the plasticization by higher condensable molecules (e.g., CO₂) and aging of polymeric membrane, cross-linking of polymer chains via ultraviolet and ion beam radiations, thermal treatment, and chemical modification is applied.

For an active membrane, such as a catalytic one used in selective oxidation of CO, the most important requirements for catalyst are (1) highly selective CO oxidation activity at low temperatures and (2) a wide temperature window for a greater than 99 % conversion of CO (Guerreiro et al. 2006). To achieve high biodiesel yield via catalytic membrane reactor operation, development of cheap and very active heterogeneous catalysts is also necessary. As environment for separation sometimes is very harsh, materials' chemical and mechanical stability become critical to biofuel production by membrane operation. One typical case is biodiesel production using membrane reactor, where viscous nature of feed limits the membrane to tubular ones made of inorganic materials (e.g., Al₂O₃/TiO₂ ceramic) (Park et al. 2004). Additionally, strong acid or base catalysts during biodiesel production also limit the selection to inorganic membranes with high resistance to degradation and corrosion.

The challenges faced by porous membranes, such as MF in sterile separation product from yeast and microbial culture, the high concentration microbes, and correspondingly high level of cell debris, can cause fouling of membrane systems. Similar situation happens in biodiesel transesterification due to oil droplets. Considerable effort is being devoted to developing new membrane modules with improved mass transfer characteristics for microfiltration processes (Reis and Zydney 2001).

Biogas

Ivo Vankelecom¹ and Muhammad Waqas Anjum²
¹Centre for Surface Chemistry and Catalysis, KU Leuven, Leuven, Heverlee, Belgium

²School of Chemical and Materials Engineering, National University of Science and Technology, Islamabad, Pakistan

Fossil fuels are still the primary source of energy by preference. However, as fossil fuels become more and more expensive with the possibility of depletion of resources, the quest for alternate sources of energy is gaining attention. In this

Biogas, Fig. 1 Schematic diagram of the anaerobic digestion process for biogas generation (Modified from Basu et al. 2010)

whole situation, anaerobic digestion of biological resources and biological waste could be a promising alternative energy carrier.

Natural gas normally consists of 90–95 % methane, but in biogas this composition is reduced to 50–65 % making it a low-grade natural gas which is the product of neutral decomposition of organic substance of animal or plant origin due to anaerobic bacterial activity. The plants used for biogas production are normally referred to as anaerobic digesters or anaerobic fermenters. The resources used for biogas production include kitchen waste, dry poultry droppings and animal excrements, remnants of food processing, and slaughterhouse leftovers. Four ingredients needed for biogas production are organic matter, bacteria, anaerobic conditions, and heat. In a controlled reaction system, the gaseous mixture thus produced can contain up to 70 % of biohydrogen and biomethane, respectively, that can be used for commercial applications (Harold 2007).

The anaerobic digestion process can be classified into different sets of complex reactions, as shown in Fig. 1. Production of biohydrogen and

biomethane from organic wastes consists of mainly three steps including hydrolysis, acetogenesis, and methanogenesis. Organic substrates can be converted to biogas by a diverse group of microbes using multienzyme (cellulases, amylases, lipases, proteases, etc.) systems.

Organic material is fed into digesters after grinding to an appropriate size. In the digesters, these substrates are heated and agitated leading to production of biogas which is collected in a biogas container. This gas is fed into an electric generator which produces electricity and heat.

Biohydrogen generated in fermentation processes (e.g., anaerobic fermentation, photofermentation, dark fermentation) has hydrogen and carbon dioxide as major ingredients. On the other hand, biomethane produced by anaerobic digestion of biological wastes has 38–40 % carbon dioxide with smaller amounts of hydrogen sulfide along with trace amounts (ppm) of hydrogen, nitrogen, oxygen, and volatiles with 55–60 % methane as a major part (Rasi et al. 2007). Biogas has a calorific value of 35–44 kJ g⁻¹, which is comparatively higher than other energy resources

Biogas, Fig. 2 Possible applications of biogas as energy resource (Modified from Basu et al. 2010)

like petrol, diesel, or LPG and solid fuels like coal, charcoal wood, etc. Biogas is a potential source of environmentally benign, clean, and cheap alternative energy. However, the presence of incombustible and acid gases, like CO_2 , not only reduces its calorific value, but their corrosive nature restricts its transportation. One of the many trace components includes silicone containing compounds. Commonly occurring siloxanes in biogas are known as volatile methyl siloxanes (VMS) that include cyclic tri-, tetra-, and pentasiloxane, as well as linear di-, tri-, tetrasiloxane. After combustion, undesirable microcrystalline quartz and pentasiloxane are produced as they cause the wear & tear of engines and turbines. Purified biogas can be used as a feed to fuel cells or for domestic applications and power generation. Figure 2 represents the possible applications of biogas (Basu et al. 2010).

Biogas Production

Marco Scholz

Aachener Verfahrenstechnik – Chemical Process Engineering, RWTH Aachen University, Aachen, Germany

Biogas mainly consists of methane and carbon dioxide and is saturated with water. Minor components such as hydrogen sulfide and ammonia are also present in the raw biogas. Biogas is produced in on-farm fermenters in the agricultural production where crops or manure are digested, in sewage plants, and by landfills. It can either be used to operate a combined heat and power engine on site or as natural gas substitute when upgrading the raw biogas. Using a combined heat and power engine (CHP) can be efficient if the produced heat is utilized (e.g., district heating). However, the heat can often not be used. Hence, upgrading the biogas and injecting the purified gas to the natural gas grid is an interesting alternative compared to onsite electricity production by CHPs. In order to upgrade biogas carbon dioxide, hydrogen sulfide and water vapor have to be removed prior to grid injection. The term upgrading particularly refers to the removal of carbon dioxide as it is the main gas component to be removed from the methane-rich raw biogas. The upgraded biogas can be utilized as a natural gas substitute. Hence, it can

drive large-scale, central gas turbines or combined heat and power cycles in which the produced heat can be used. In addition, upgraded biogas can be utilized as fuel for vehicles or it can be used as feedstock for the chemical synthesis (Baerns et al. 2006).

Various technologies exist to upgrade biogas (Hofmann and Plaettner 2006). Physical and chemical absorption and adsorption are well-established technologies to upgrade biogas. Recently, gas permeation membranes became important in biogas upgrading (Scholz et al. 2013), as gas permeation processes are energy efficient, easy to handle, and robust, which is important in the on-farm operation. In principle, cryogenic separation could also be applied to separate methane and carbon dioxide, but due to the low raw gas flow rates (typically less than 2,000 m³ (STP)/h), it is uneconomical. Recently, a membrane cryogenic process was designed which is able to compete with

established technologies such as amine scrubbing (Pentair 2013) (Table 1).

There is no international standard on the gas specifications to be supplied to the natural gas grid. In general, the methane content should be higher than 96 %. Often the gas has to be supplied at elevated pressures (e.g., >10 bar). The tolerable hydrogen sulfide levels vary also depending on the country the biogas plant is operated in. The electrical and thermal energy demand to drive the upgrading process is typically in the range of 0.15–0.25 kWh/m³ (STP) and 0.3–0.8 kWh/m³ (STP), respectively. Methane recoveries, which are the ratio of the methane flow rate of the product gas to the methane flow rate of the feed gas, of more than 99 % should be achieved to minimize the environmental impact and to enhance the process economics. However, the product gas requirements have to be analyzed for each individual biogas upgrading plant.

Biogas Recovery

Ivo Vankelecom
Centre for Surface Chemistry and Catalysis,
KU Leuven, Leuven, Heverlee, Belgium

The constant increase in energy demand, coupled with the depletion of fossil fuels, is a concern that cannot be ignored in the industrial and highly populated world of today (Basu et al. 2010). Biogas production is a very promising source of renewable energy that still offers further exploitation of its potential (Scholz et al. 2013). Essentially, microbially controlled biogas production is an already existing part of the global carbon cycle, releasing an estimated 590–800 million tons of methane to the atmosphere (Bond and Templeton 2011). Current biogas recovery systems seek to exploit these processes in order to produce energy from sewage wastewater, animal manure, crop straws, or mixed agricultural wastes (Chen et al. 2012; Rasi et al. 2011). Usually, a system for biogas recovery consists of four components: a collection system which helps transfer the biogas source to the anaerobic digester, the anaerobic

digester in which the methane production takes place, a biogas collection system providing piping of biogas to a combustion device, and a gas use device where biogas is combusted to produce heat or electricity (Agstar 2011). Alternatively, the produced biogas can be used on site as fuel for automobiles or can be injected in the natural gas grid. In this case, the gas must be upgraded to natural gas standards, namely, 98 % methane content (AEBIOM 2009).

Although the composition of biogas varies significantly depending on many factors such as the type of digester, the average values are reported to range between 50 % and 70 % methane and 30–50 % carbon dioxide, as well as hydrogen sulfide, sulfur compounds, siloxanes, and aromatic and halogenated compounds (Rasi et al. 2007). Upgrading (purification) of biogas is highly beneficial in terms of increasing the amount of methane per unit volume of biogas, which equals an increase in its calorific value. In addition to the obvious need for removal of carbon dioxide as the major pollutant, the trace compounds have the potential to trigger ozone depletion and the greenhouse effect, reduce the quality of local air due to formation of volatile organic compounds (VOCs), and so on. Moreover, sulfur compounds corrode pipelines and combustion engines, while silicon compounds oxidize and are deposited on engine parts (Rasi et al. 2007). Currently, biogas upgrading is largely achieved through amine scrubbing where carbon dioxide is absorbed into an amine solution, water scrubbing where carbon dioxide is absorbed to water at elevated pressures, and pressure swing adsorption where pressure of the gas mixture is changed to induce adsorption and desorption of one gas species. These technologies are in general more energy intensive and polluting than membrane technology (Basu et al. 2010; AEBIOM 2009; Scholz et al. 2013). Polymeric membranes have gained a share in the separations market, as opposed to the inorganic membranes which are expensive and brittle. Some commercial polymeric membranes such as SEPAREX (cellulose acetate) of UOP and polydimethyl siloxane (PDMS) have

already proven or were reported to operate successfully in separation of carbon dioxide or siloxanes and VOCs, respectively. However, the separation of hydrogen sulfide still remains a difficult and interesting issue for membrane research. Mixed matrix membranes composed of inorganic particles distributed throughout a polymeric matrix are promising alternatives thoroughly investigated for these separations (Basu et al. 2010).

- industrial waste. The composition of biogas varies from the origin of the anaerobic digestion process, and the main components are methane (CH₄) and carbon dioxide (CO₂) as shown in Table 1 (Rasi et al. 2007). Biogas has a very high-energy potential due to the presence of methane (CH₄) and thus is a great source for renewable energy production, which can be used for heating, combined heat and power (CHP) generation, vehicle fuel, fuel cell, and substitute natural gas. Depending on the different end uses, the specific biogas treatment should be executed. For the applications as vehicle fuels and natural gas grid injection, CO₂ should be removed from the raw biogas, i.e., biogas upgrading, to reduce the corrosion caused by the acid gases and increase the Wobbe index which is directly proportion to the methane concentration. However, biogas upgrading process will add extra costs into the biogas production. Thus, an optimized upgrading technology in terms of low energy consumption and high efficiency should be developed to reduce the biogas production cost. Moreover, the minimum emission of CH₄ should also be addressed since methane has a greenhouse effect of around 23 times higher than that of CO₂.

Different techniques such as pressure swing adsorption (PSA), physical absorption (e.g., water scrubbing), chemical absorption (e.g., amines), and membrane system have been investigated for biogas upgrading. The choice of a suitable technology is mainly dependent on the specific condition at a plant, such as availability of low price for heating, electricity, and water, as well as the amount of gas to be handled. Today, most of biogas upgrading plants in Sweden are still using PSA even though the methane content in the upgraded gas is low (96 %) and methane loss is quite high (3–10 %), while some plants using water scrubbing technique will additionally produce a lot of wastewater, and electricity consumption is also quite high. Membrane system could be favorable for biogas upgrading due to a series of advantages including the safety and simplicity of the operation and easy maintenance without any hazardous chemicals (Makaruk et al. 2010). Figure 1 shows a schematic diagram of membrane system for biogas upgrading.

Biogas Upgrading

Xuezhong He
Department of Chemical Engineering, Norwegian University of Science and Technology, Trondheim, Sør-Trøndelag, Norway

Biogas is produced in anaerobic digesters from biodegradable wastes such as sewage sludge, manure, organic fraction of household, and

Biogas Upgrading, Table 1 Typical gas composition from different sources (Rasi et al. 2007)

Process	Composition (vol, %)					H ₂ S/SO ₂ (ppm)
	CO ₂	CH ₄	N ₂	O ₂	H ₂ O	
Farm biogas plant	37–38	55–58	<2	<1	4–7	32–169

Landfill	37–41	47–57	<1	<1	4–7	36–115

**Biogas Upgrading, Fig. 1** A schematic diagram for biogas upgrading process by membrane systems

As illustrated in the above flow sheet, H₂S and water vapor must be removed before feeding into the membrane system. Compression of gas may vary depending on whether it goes to natural gas grid (<80 bar) or will be used for vehicle fuel (~200 bar). The main challenge of a membrane system is the pretreatment of biogas to protect the membrane materials, especially for the biogas produced from the sewage treatment plants and landfill sites where it usually have a lot of malicious gas components. Polyvinyl amine (PVA)/polyvinyl alcohol (PVA) blend fixed-site-carrier (FSC) membranes for biogas upgrading have been investigated by Deng et al. (Deng and Hägg 2010). Their results indicated that a membrane process with a CH₄ recovery of 99 % at a low operation cost could be designed to achieve the

specification of natural gas network distribution, which makes this environmentally friendly technology more competitive compared to the other conventional technologies currently used. Makaruk et al. pointed out that membrane system provides enough flexibility for heat integration within biogas plants (Makaruk et al. 2010), and the expected energy requirement for a single-produced cubic meter of natural gas substitute is estimated to be around 0.3 kWh, which is close to the values reported in an industrial scale demonstrator for membrane biogas upgrading plant at Bruck an der Leitha in Austria (Miltner et al. 2008). Moreover, a new carbon membrane company MemfoACT (<http://www.memforact.no>) was launched in 2008 in Norway, which mainly focuses on the biogas upgrading using

their patented hollow fiber carbon molecular sieve membranes. Their contributions could promote to bring this technology into the commercial application in the near future.

Biogas Upgrading by Membrane Processes

Marco Scholz

Aachener Verfahrenstechnik – Chemical Process Engineering, RWTH Aachen University, Aachen, Germany

Biogas upgrading, which is the removal of carbon dioxide from a methane-rich raw biogas, can be accomplished using membranes. Gas permeation membranes or membrane contactors can be applied to remove carbon dioxide. Membrane contactors are still under investigation, while gas permeation modules are applied in commercial biogas upgrading plants (Scholz et al. 2013). In principle, organic as well as inorganic membrane materials have excellent selectivities to separate carbon dioxide and methane. However, Baker (2001) reports that only a limited number of membrane materials are commercially available as membrane modules, and all these membranes are made out of polymers. For commercial polymeric membranes, carbon dioxide permeates faster

through the membrane than methane. Thus, the methane-rich product gas is supplied on the retentate side of the membrane stages.

Some commercially available membrane materials have selectivities of as high as 60 (Scholz et al. 2013). However, by applying these membranes in a single-stage gas permeation process, significant methane losses are observed in order to achieve the required methane purity of 96 % (Rautenbach and Welsch 1993). Hence, the trade-off between methane purity and methane recovery cannot be overcome. Therefore, multi-stage gas permeation processes are required to produce a product gas with methane purities of more than 96 % while simultaneously providing methane recoveries of more than 99 %. To design an upgrading process with high methane recoveries is particularly important as the methane recovery determines the profitability of the biogas upgrading plant and competing upgrading processes such as amine scrubbing or pressure swing adsorption show high methane recoveries.

The driving force to operate the gas permeation process can either be provided by a feed-side compression or by a permeate-side vacuum pump. As the carbon dioxide content in the raw gas can be as high as 50 % and the methane-rich product gas should be provided at elevated pressures, the compression prior to the gas permeation system is preferred over a system operating with subambient pressure on the permeate side. Here, the compressor provides both the driving force for the permeation of carbon dioxide and the elevated pressure of the product gas for natural gas grid injection.

Gas permeation membranes can be combined with conventional gas separation technologies in membrane hybrid processes. Recently, a membrane cryogenic process was reported, which has high methane recoveries (Pentair 2013). In this particular process, the gas permeation stage is applied to provide the methane-rich product gas. Since the permeate stream of the membrane stage contains significant quantities of methane, the permeate stream is compressed up to 20 bar and fed to a cryogenic separation unit, which operates at –24 °C. Here, the carbon dioxide fraction is

liquefied and a methane recovery of 100 % can be obtained.

Another option to upgrade biogas is to use a single-stage membrane process and to supply the upgraded biogas in one step. The permeate of the membrane stage, which contains significant amounts of methane, is combusted in a combined heat and power engine (Makaruk et al. 2010). The combined heat and power engine requires at least a methane level of 30 % so that raw biogas can be mixed with the permeate stream to adjust the methane level. By applying this particular process design, the electrical energy demand to drive the upgrading process can be provided by the gas engine. However, the produced heat cannot be used efficiently.

Biohybrid Artificial Liver (BAL)

Sabrina Morelli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

A biohybrid artificial liver (BAL) is a bioartificial device which consists of functional liver cells supported by an artificial cell culture material. It incorporates hepatocytes into a bioreactor in which the cells are immobilized, cultured, and induced to perform the hepatic functions by processing the

blood or plasma of liver failure patients. BAL provides temporary support for patients waiting for an allogeneic liver transplant, and since the liver can regenerate, the temporary support provided by BAL may allow time for liver regeneration.

The bioreactor is an important component of BAL, because it determines the viability and function of the hepatocytes within it. A successful and clinically effective bioreactor should mimic the structure of the liver and provide an in vivo-like microenvironment for the growth of hepatocytes, thereby maintaining the cells' viability and function to the maximum extent. The important issues are the choice of cell sources and the design of the bioreactor (Ding and Shi 2011). The cell sources provide liver-specific functions, such as detoxification, drug metabolism, and protein synthesis, while the bioreactors maintain the viability and function of cells. More efforts are now underway in search for the best cell resource and best design of bioreactors.

Considering the several functions that the liver performs, the bioreactor for BAL devices has to ensure the rapid detoxification of neural and hepatic toxins, the return of liver-specific hepatotrophic factors, as well as liver-specific coagulation factors, back into patient's blood, and the maintenance of liver cell detoxification and synthetic functions until liver tissue regeneration or organ transplantation.

One of the most promising bioreactors is the membrane bioreactor. Polymeric membranes in flat and hollow fiber configuration with different morphology and chemical–physical properties have been used in BAL devices (De Bartolo and Bader 2001; Kamlot et al., 1996; Kasuya and Tanishita 2012). Most of the extracorporeal BALs have not only used cellulose and polysulfone derivatives but also native and modified polypropylene membranes. Morphological (e.g., pore size, pore size distribution, and roughness) and physicochemical membrane properties (e.g., surface charge, wettability, and surface free energy) affect all the adhesion and metabolic functions of hepatocytes.

Hepatocytes have been cultured in membrane bioreactors in different configurations: between flat sheet membranes in a sandwich configuration; in the lumen of hollow fiber membranes entrapped

in a collagen layer; in the shell of hollow fiber membranes in monolayer, aggregate, or spheroid structure and attached to microcarriers; in a network of hollow fiber membranes with different functions; in a spirally wound device in which hollow fibers are used to provide oxygen to the cells; in multibore capillaries; microencapsulated and in an oxygen-permeable membrane rotating system under microgravity conditions.

Several designs of BAL devices that are different in configuration, cell source, and culture technique have currently undergone clinical trials (Morelli et al. 2010).

Biohybrid Artificial Liver (BAL) Systems

Sabrina Morelli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

A biohybrid artificial liver (BAL) system is an artificial extracorporeal supportive device which

represents an important therapeutic strategy for patients with acute liver failure.

Generally, a BAL system consists of functional liver cells supported by an artificial cell culture material. In particular, it incorporates hepatocytes into a bioreactor in which the cells are immobilized, cultured, and induced to perform the hepatic functions by processing the blood or plasma of liver failure patients. The BAL system acts as a bridge for the patients until a donor organ is available for transplantation or until liver regeneration. The development of a BAL system involves many design considerations. It must provide (1) an adhesion support to the cells; (2) adequate mass transfer of oxygen, nutrients, and toxic substances from the blood or plasma of patients to the cell compartments and proteins, catabolites, and other specific compounds produced by cells from the cell compartment to the blood or plasma; (3) immunoprotection of cells; and (4) biocompatibility. BAL devices are classified by the cell source, the type of culture system for the hepatocytes, and the configuration of the bioreactor.

Several BAL systems have been evaluated preclinically in in vitro experiments and in large animal models of liver failure (Morelli et al. 2010). Currently, different types of BAL devices are in various stages of clinical evaluation, and some of them are listed in Table 1 (van de Kerkhove et al. 2004).

Many of these devices use hollow fiber membranes (HFMs) as supports for the cultured hepatocytes and as immunoselective barriers between the plasma of the patients and the hepatocytes used in the bioreactor. Membranes also permit the transport of nutrients and metabolites to cells and the transport of catabolites and specific metabolic products to the blood. In the membrane bioreactors, mass transfer is determined by the molecular weight cutoff (MWCO) or pore diameter of the membrane and occurs by diffusion and/or convection in response to existing transmembrane concentration or pressure gradients. Most of the bioreactors for BAL systems use membranes with MWCO ranging from 70 to 100 kDa that allow the transport of serum albumin but exclude proteins with high MW such as immunoglobulins and cells.

One of the first clinical devices using HFMs was developed by Sussman and coworkers, namely, the extracorporeal liver-assist device (ELAD) in which the human hepatocytes were located outside the hollow fiber and blood flows through the lumen of the hollow fibers. This device was commercialized by Amphioxus Cell Technologies (Sussman et al. 1992). HepatAssist Circe Biomedical is the most clinically advanced system of its kind. It is an extracorporeal cell-based bioartificial liver device, based on the use of an open membrane hollow fiber bioreactor (Demetriou et al. 1995). In this system, hepatocytes are loaded into the extracapillary space, and the patient's plasma flows through the capillary lumina of membranes. A more complex system is the liver support system (LSS) or the modular extracorporeal liver system (MELS) which consists of a bioreactor with four interwoven independent capillary membrane systems that serve different functions (Gerlach et al. 1994). The BLSS is a hollow fiber device that uses porcine hepatocytes embedded in a collagen matrix (Patzer et al. 2002). The Academic Medical Center Bioartificial Liver (AMC-BAL) developed by Flendrig et al. uses a three-dimensional, spirally wound, nonwoven polyester matrix for hepatocyte attachment with integrated hollow fibers for oxygen delivery to the cells (Flendrig et al. 1997). Another BAL system that is currently in clinical

testing is a bioreactor from TECA Corp. in which a polysulfone membrane compartmentalizes porcine hepatocytes (Ding et al. 2003).

Biohybrid Artificial Liver Systems

► Bioartificial Liver Support System (BLSS)

Biohybrid Membrane Systems

Sabrina Morelli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Biohybrid membrane systems are engineered systems based on the combination of biological units, cells, or tissues, immobilized on an artificial structure, the membrane. In these systems, membranes act as instructive materials which are capable of supporting tissue/organ formation. Cells have to make an intimate contact with the surface of the membrane but also to develop close cell-cell connections, which is a precondition for their survival and high functional activity.

Among polymeric materials, membranes in flat and hollow fiber configuration are the most attractive in the use of biohybrid systems for their characteristics of stability, biocompatibility, and selective permeability. Polymeric membranes could mimic the extracellular matrix with which cells interact allowing the organization of the cells into a three-dimensional architecture. The membranes are able to modulate the adhesion, proliferation, and differentiation of cells which are fundamental processes for tissue regeneration by governing the mass transfer of molecules that generate a precisely controlled microenvironment

that mimic the specific features of in vivo environments.

Biohybrid membrane systems are successfully applied in the field of tissue engineering and regenerative medicine (Morelli et al. 2009). For the development of functional biohybrid membrane systems, a number of issues need to be addressed: morphological, physicochemical, mechanical, and transport properties of the membrane, the optimal density of immobilized cells, the interaction of cells with the membrane, the differentiation of cells, as well as the maintenance of viability and metabolic functions in vitro membrane constructs.

Different types of biohybrid membrane systems have been proposed for the reconstruction and/or regeneration of many organs and tissues (e.g., the pancreas, liver, kidney, skin, and bone Scharp et al. 1994; Saito et al. 2006; De Bartolo et al. 2009; Ding and Shi 2011; Gentile et al. 2011).

Currently, biohybrid membrane systems are also developed for the creation of a biomimetic microenvironment for neural tissue engineering since they may be used for the in vitro simulation of human brain functions. Semipermeable hollow fiber membranes are widely used as guidance channels in promoting in vitro and in vivo neuronal regeneration (Zhang et al. 2005; Morelli et al. 2010, 2012).

Generally, biohybrid membrane systems could not only have a role in the replacement of injured organ or tissue but also accelerate the development of new drugs that may cure patients as an alternative to animal experimentation.

Bioinspired Membranes

Zhongyi Jiang, Yifan Li and Hong Wu
School of Chemical Engineering and Technology,
Tianjin University, Nankai, Tianjin, China

Bioinspired membrane can be thought of as a comprehensive name for a big family of artificial membranes of which the design originality arises from biological phenomena and principles in nature. Compared with biomimetic membrane, bioinspired membrane is a much broader term (Rawlings et al. 2012), because a bioinspired membrane does not necessarily employ biological membrane or biologically occurring thin film as

the archetype. On the one hand, the membrane materials (organic, inorganic, or organic-inorganic hybrid) can be synthesized by borrowing the fundamental principles of the materials processing in nature. On the other hand, the advancement in any branch of biological materials science related to structure, function, and structure-function relationships can be employed and incorporated to rationally design the structure or function of bioinspired membrane. As a result, the membrane preparation is usually conducted under very mild conditions (aqueous solution, ambient temperature and pressure, neutral or near neutral pH, etc.), the membrane materials are often easily available and biodegradable, the membrane structure can be finely tuned, and the membrane often displays multiple functions and high application efficiency. To some extent, the bioinspired membrane can be viewed as next-generation membrane.

At present, several bioinspired platform techniques based on fascinating biochemistry and biology have been developed. For example, inspired by formation process of biosilica, a platform technique called “biomineralization” or “biomimetic mineralization” was developed to fabricate polymer-inorganic nanohybrid membrane (Pan et al. 2010). By using biomolecules as catalyst and/or template, silica nanoparticles were in situ generated and well dispersed in a polymer matrix, and the as-prepared hybrid membrane synergistically combined the advantages of two components. Another platform technique example is “bioadhesion” or “biomimetic adhesion.” This technique originated from mussel-inspired catecholic chemistry, which was successfully utilized to construct ultrathin and stable active layer of dense composite membrane (Li et al. 2009). The other techniques are mostly based on self-assembly, in particular layer-by-layer (LBL) assembly. LBL assembly technique provides a powerful platform to manipulate multiple interactions, such as covalent bond, hydrogen bonding, charge transfer, hydrophobic, host-guest, and coordination bond interactions (Matsusaki et al. 2012), so as to prepare membrane with precisely tailored nanostructures (i.e., thickness, free volume, hydrophilicity, etc.).

Bioinspired Membranes,

Fig. 1 Concept of nanotube-based hierarchically structured membrane with durable high permeability and selectivity

Future effort on this type of bioinspired membrane may turn to improving the fundamental mechanism and extending the application fields. Of course, new bioinspired platform techniques will be continuously explored.

Selective transport properties and the corresponding membrane structures are another major concern in bioinspired membrane realm. In biology, the most effective membrane-mediated separation/transport processes often involve complex, nonplanar articulations of structure that are highly optimized to support the multiple functions. Inspired by the hierarchical structures in biology, rational design and synthesis hierarchical structures within membranes may offer immense opportunities for efficient molecular/ion sieving processes. For example, nanotubes have been utilized to mimic biological channels for rapid and selective molecule transport. With the aid of nanotubes, an ideal concept of vertically aligned biomimetic channels within a membrane matrix have been proposed and shown in Fig. 1, where membrane permeability, selectivity, and durability are individually manipulated by the highly permeable nanopores, the entrance chemistry of the nanotube, and the robust nonporous filling matrix. Here, the aligned nanotubes are extremely like the channel proteins inserted through cell membranes. This concept has partially come true recently (Xu et al. 2011), and it requires much more efforts to fulfill all the potentials of this concept. Also, many block copolymers have been designed to mimic the hydrophilic-hydrophobic mosaic structure of biomembrane for antifouling (Chen et al. 2011). Moreover, many efforts have been dedicated to mimicking the proton pump and ion channel so as to accelerate proton transport (Wang et al. 2012; Sharma et al. 2010). In addition to selective

transport properties, intelligent properties of membranes show great promise in membrane science and technology (Tokarev and Minko 2010). For instance, self-healing membrane, self-cleaning membrane, and many sorts of stimuli-responsive membranes have been reported (Chen et al. 2011; Wang et al. 2011b; Capadona et al. 2008; Tokarev and Minko 2010). Such smart behaviors can endow the membrane with ultra-high stability, switchable permeation flux, alternative driving force, etc. Other properties, such as mechanical strength, interface adhesion, water retention, etc., have been successfully reinforced by learning from nature (Zeng et al. 2010; Ma et al. 2010; Wang et al. 2011a). Breakthroughs in understanding how a living system works and exploring new inspiration source will ensure the sustainable development of bioinspired membrane.

Synonyms

Biorecognition substrate

A biointerface is an interface between biological material (e.g., cells, tissue) and a (commonly) synthetic substrate. Biointerfaces call for advanced design and preparation in order to match the sophisticated (bio) recognition ability of biological systems. Specifically this requires combined topographic, chemical, and viscoelastic patterns on surfaces to match proteins at the nm scale and cells at the micrometer scale (Kasemo 2002).

Biointerfaces are typically used in the fields of immunology, surgery, pathology, pharmacology, and many others either for the proliferation of cells for further application or investigative study or as a platform for cell manipulation. These studies have become even more topical upon completion of the human genome project, which has set the formidable challenge of elucidating the function of the vast amount of genomic information within the genotype of an individual.

A potential medical application of a biointerface is in the ex situ growth of skin/bone/organ tissue for subsequent transplantation. For example, burn victims can have their own replacement skin grown in a laboratory via the proliferation of their own epidermal cells upon a biointerface in a laboratory. Biointerfaces themselves can potentially be installed in situ to assist in cell regeneration, such as after surgery. For this purpose, biodegradable biointerfaces are of particular interest as they perform their function of assisting cell regeneration and are then degraded naturally into nontoxic products which are then excreted (Hook et al. 2006).

The scientific study of cells is important to improve fundamental understanding of their working process. Biointerfaces are often used as experimental platforms to study various properties of cells. For instance, neuronal cells are electrically excitable cell that processes and transmits information through electrical and chemical signals. The growth of these cells on specially designed biointerfaces has allowed scientists to directly investigate their signal transmission process (Robinson et al. 2012).

The fabrication of various biointerfaces is of particular interest for stem cell research. Stem cells can differentiate into a variety of different

cell types depending upon their environment (Pittenger et al. 1999). Therefore, the careful design of particular biointerfaces can promote stem cell differentiation into a desired cell type. For example, stem cells adsorbed on harder surfaces tend to differentiate into bone-like cells (Engler et al. 2006).

Introduction

Biological membranes are enclosing or separating membranes that act as selectively permeable barriers within living things. Biological membranes have dynamic structures composed of phospholipid molecules, proteins, and carbohydrates (Brown and London 1998; Diamond and Wright 1969; Lee 2003). Steroid cholesterol is also found in the biological membranes of eukaryotic organisms.

The phospholipid component of the biological membrane plays an important role in the property of biological membranes. A phospholipid layer consisted of a hydrophilic head that interacts with polar fluids (e.g., water), and its hydrophobic tail always meets with the hydrophobic tail of another layer (forming a phospholipid bilayer or a liposome) or its own (forming a micelle). This structure maintains the fluidity of cells and organelles. The embedded, integral, and peripheral proteins of biological membranes are used in communication and transportation of chemicals and ions. Typically, the phospholipid bilayer acts as an impermeable barrier to most molecules and molecules can only cross the membrane with the aid of proteins.

Biological membranes, in the form of cell membranes (i.e., plasma membranes), are selectively permeable to ions and organic molecules and thus could control the movement of substances in and out of cells. Cells also contain intracellular membranes, which act as the boundary of various intracellular organelles, e.g., the nucleus and the mitochondria.

Biomaterial

Loredana De Bartolo

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

A biomaterial is any material in contact with a biological system. The first nonbiological material entered in contact with the human body seem to date back to the prehistory 9000 years old with the “Kennewick Man,” who had a spearpoint embedded in his hip. This spearpoint was the first foreign material implant, which was “tolerated” by the body (Ratner et al. 2012). Although the use of biomaterials dates back to the ancient time, the study of biomaterials is about 60 years old.

Biomaterials can be classified on the basis of its (i) source in natural or synthetic materials if they are from nature or synthesized in laboratory, respectively; (ii) chemical nature in organic, inorganic, and composites; and (iii) degradation properties in biodegradable and nonbiodegradable. They can be used in biomedical devices for the replacement of an organ function or implanted into the body for the replacement of tissue, organ, or body parts. Biomaterials are also used every day in dental applications, surgery, and drug delivery (Williams 2009).

Natural-based polymers offer the advantage of being similar to extracellular matrix components, and they have binding sites for cells and adhesion molecules so that they usually avoid immunological reactions and toxicity. Their principal disadvantage lies in the development of reproducible production methods, because their structural complexity often makes modification and purification difficult. Additionally, significant batch-to-batch variations occur because of their “bio preparation” in living organism (plants, crustaceans) while their mechanical properties are also limited. Chemical modification and cross-linking are common methods for altering mechanical properties such as elasticity and tensile strength of natural materials which are often not appropriate for dynamic physiologic environments. The most frequently used natural biomaterials are the collagen derived from connective tissues of animals, fibrinogen obtained from plasma, and other proteins of ECM. Among natural biomaterials, polysaccharides are also frequently used. These natural polymers include agarose, hyaluronan, chitosan, and alginate. They are derived from plant (seaweed) or animal origin and are used as hydrogels to support wound healing and also cell growth and differentiation (Mano et al. 2007).

Synthetic biomaterials different from natural materials can be synthesized to give various properties and have high reproducibility, availability, lot-to-lot uniformity, and constant quality. They have a well-known structure and properties so that mechanical properties, degradation rate, shape, and composition can be adjusted to the specific application. However, the biocompatibility and immune reactions are the big concern because they often lack sites for cell adhesion therefore their interactions with cells could be questionable. Synthetic biomaterials include biodegradable polymers as poly(lactic-co-glycolic acid) (PLGA), poly-lactic acid (PLA), polycaprolactone (PCL), poly(ethylene glycol) (PEG), etc. and synthetic polymers (e.g., polyurethane, polyetheretherketone, polyethylene, polyvinylidene fluoride, polyvinyl alcohol, polymethyl methacrylate, polydioxanone, etc.). For example, PLGA is one of the most frequently used biomaterials applied in neural, bone, and

cartilage tissue engineering for its degradation rate that can be modulated. PLA is fast reabsorbed and widely used in tissue engineering applications alone or blended with other polymers. PCL is a very good elastic biodegradable polymer that finds several applications in tissue engineering. PEG that is used in pharmaceutical technology to modulate the degradation and absorption of bioactive proteins is also frequently used in bone, cartilage, nerve, liver, and vascular tissue engineering. Peptide-based biomaterials (e.g., the tripeptide Arg-Gly-Asp, RGD) consisting of short amino acid sequences exhibit cell-binding sequences found in the extracellular matrix natural proteins. Ceramic-based biomaterials that are totally or partly inorganic are applied in bone tissue engineering. Mostly they are shaped with heat-forming porous, brittle materials. Hydroxyapatite and tricalcium phosphate owing to their structural similarity to the mineral phase of bone are used alone or in combination with organic polymers like PLA, PLGA, collagen, or chitosan in the bone replacement or regeneration (De Bartolo and Bader 2013; Morelli et al. 2015). Metals like alumina and titanium alloys that are bioinert materials are used as implant materials where implants are subjected to extreme mechanical load, like articular prostheses, dental implants, or heart valves.

Biomimetic Membrane Approach

N. M. Kocherginsky
Biomime, Urbana, IL, USA

Biomimetic membrane approach is based on artificial membranes which imitate fundamental properties and functions of biological membranes. Biomimetics develops simple and efficient synthetic systems that mimic the formation, structure, or function of biological materials, leading to new, more efficient, and cheap applications. Major potential applications of biomimetic membranes are drug delivery, high-throughput screening, sensors, and separation and purification, possibly coupled with chemical synthesis (Hélix-Nielsen 2012). The same membrane can serve an opposite purpose and be used as an experimental model of biomembranes. The term biofunctional membrane is more appropriate for the membranes, which include biological components, such as specific enzymes, aquaporin, antigens, etc.

Biological membranes have a lot of different specific functions but all of them separate either two aqueous phases or an external gaseous and internal aqueous phase. Three major chemical components of biological membrane are proteins, lipids, and polysaccharides, and selective permeability is based on direct diffusion, facilitated transport with carriers, and penetration through the channels. Coupling with various energy sources, including light, adenosine triphosphate, and different ion concentrations separated by the membrane aqueous solutions, leads to the transmembrane active transport. Membrane processes can be controlled by temperature, transmembrane voltage, biochemical mediators, and drugs.

Amphiphilic molecules are usually able to spontaneously form liquid crystal structures.

These self-assembled structures, especially lipid monolayers, multilamellar vesicles, unilamellar liposomes, and bilayer lipid membranes can be used as models of biomembranes. To improve their stability, which is important for practical applications, lipid membranes are often immobilized on a solid support, which may be metal, glass, semiconductors, and polymers. The well-known example is Langmuir-Blodgett films. Lipids or their analogs may have an additional anchor group for tethering to a support. Sulfhydryl or disulfide groups are often used for tethering to the metals such as gold or silver, while methyl- and methoxy-substituted silane groups – for tethering to glass, quartz, silica, and mica. Micro- and nano-porous solid supports, including hydrophobic membrane filters, are also used to stabilize thin and nonstable bilayer lipid membranes.

Though the thickness of lipid membranes (~ 50 Å) and some other structural properties are similar to the characteristics of biological membranes, electrical conductivity and permeability for inorganic ions are often four orders of magnitude less than those of biomembranes with aqueous channels.

Nitrocellulose microfilters with pores filled with fatty acids and other lipid analogs are another type of stable biomimetic membrane (Kocherginsky and Lvovich 2010). These impregnated filters have nanolayers of water covering the internal pore surface and separating nitrocellulose and liquid crystal structures inside the pores. Aqueous nanolayers imitate aqueous channels in biomembrane and have cation/anion selectivity due to the presence of carboxylic groups immobilized on the nitrocellulose polymer chains. Electric resistance and many other physically independent properties of these membranes, including direct permeability of water, nonelectrolytes and respiratory gases (O_2 and CO_2), and other properties recalculated for 50 Å thickness, are very similar to parameters for biological membranes. Low molecular mass carriers can be dissolved in the impregnating oils, leading to imitation of secondary active transport of metal ions and even electrons, driven by transmembrane difference of pH. Kinetics may be

controlled by temperature-induced phase transitions and even membrane-active organic cations. The process may be used for water purification. Nitrocellulose-based biomimetic membranes may also be used in potentiometric drug sensors (sensitivity often is $10^{-5}M$), and combination with electrochemical tests makes this system attractive in the high-throughput drug screening, such as Parallel Artificial Membrane Permeability Assay (PAMPA).

Biomimetic Membranes

Zhongyi Jiang, Jing Zhao, Shaofei Wang,
Dong Yang and Hong Wu
School of Chemical Engineering and Technology,
Tianjin University, Nankai, Tianjin, China

Biomimetic membrane is designed and fabricated by imitating the composition, structure, formation process, as well as functions of biological membrane. As we know, biological membrane is the vital structural basis in organism, on which the essential life activities in cell take place. The asymmetric and hierarchical bilayer structure formed by the in situ self-assembly of amphiphilic phospholipid and functional proteins (Nielsen 2009) ensures the biological membrane take important roles in keeping the environmental stability of cell, participating in the multiple interactions of different cells, and efficiently achieving the conversion of energies, the signal transduction between cells, as well as the conversion and transmembrane transport of some substances (Zhu et al. 2011). Biological membrane has a very sophisticated structure consisting of abundant

species of lipids and proteins, which is difficult to imitate completely due to the constraints of current science and technologies (Eeman and Deleu 2010). As a simplification and transition, biomimetic membranes containing part of (not all) the key components or characteristics of biological membrane are being actively developed in the last few decades.

Biomimetic membranes can be divided into two categories in terms of structural morphology: freestanding membrane and supported membrane. The freestanding membrane is often utilized for theoretical investigation purpose, in other words, as a simplified model for studying the structure and function of biological membranes. This type of biomimetic membranes mainly includes the lipid monolayer membrane and the bilayer lipid membrane or named black lipid membrane (BLM) (Eeman and Deleu 2010; Kim et al. 2012). The BLM is suitable for investigating membrane phase behavior and membrane processes such as membrane fusion and molecular recognition for its closer structure with biological membrane, while the lipid monolayer is suitable for mimicking and evaluating the insertion of amphipathic compounds (Eeman and Deleu 2010). The biomimetic membrane has provided an effective platform for exploring the complex structure and function of biological membrane, even though further endeavors both in biological science and fabrication technology are still needed.

The supported membrane often contains a bilayer residing onto a solid substrate, which delicately ameliorates the weak stability and short lifetime of BLM (Li et al. 2012). Furthermore, the self-assembly of block copolymer (block polymer membrane, BPM) as another approach to form the bilayer can be an alternative of BLM for its higher stability, controllability, and ability to prevent the direct contact of embedded proteins to solid substrate, which otherwise will inactivate the proteins (Duong et al. 2012; Nielsen 2009). The supported BLM or BPM can be prepared by several methods, of which vesicle collapse technique is commonly used (Eeman and Deleu

2010). In addition to act as model of biological membrane for investigating protein-lipid interaction, this type of biomimetic membrane performs well as functional membrane in various fields by incorporating different functional proteins: (1) energy conversion (energy converter, energy-production devices), (2) signal transduction (biosensor and bioanalysis), and (3) substance transport and conversion (drug delivery, immobilized enzyme catalysis, and membrane-based separation). To further exploit the application efficiency and area of biomimetic membrane, more efforts may be devoted to the following two aspects: (1) utilize channel proteins directly for the preparation of biomimetic membrane while acquiring the good control over the channel density and the protein activity and (2) deepen the insight into the structure-function relationship of membrane proteins.

Membranes used for bioreactors

Introduction

A bioreactor membrane is a synthetic organic or inorganic membrane used for solid-liquid separation in membrane bioreactors (MBRs). The membranes can be pressure driven (microfiltration, ultrafiltration, nanofiltration, and so on) and osmotically (forward osmosis) or thermally driven (membrane distillation); however, pressure-driven membranes are currently more popular. In most cases, MBR refers to the combination of a membrane process with a suspended growth bioreactor that is applied for water/wastewater treatment and/or for other purposes (e.g., fermentation). When used in wastewater treatment, sound retention of suspended solids by bioreactor membranes enables the distinctive advantages of MBRs, including a reduced footprint, an independent control of sludge retention time and hydraulic retention time, a higher biomass concentration, and a high-quality effluent (Judd 2008; Wang et al. 2008; Meng et al. 2009).

Bioreactor membrane characteristics such as pore size, porosity, surface charge, roughness, and hydrophilicity/hydrophobicity have been proven to impact on MBR performance, especially on membrane fouling (Meng et al. 2009). A series of organic and inorganic membrane materials, including polyvinylidene fluoride, polyethylene, polyacrylonitrile, polyethersulfone, polytetrafluoroethylene, polypropylene, polysulfone, cellulose acetate, aliphatic polyamides, aluminum, zirconium, and

titanium oxide, have been used in bioreactors, and an ideal material should have low affinity with biopolymers/foulants, sound mechanical strength, and good separation efficiency and is nonbiodegradable and cost-effective (Su et al. 2014).

In recent years, dynamic membranes have been investigated in MBRs in order to improve membrane performance (Meng et al. 2009). Contrast to conventional synthetic bioreactor membranes, dynamic membranes can be formed by filtering a solution containing either inorganic or organic materials (particulate, colloidal, and even soluble substances) through a coarse support material (Fan and Huang 2002). The separation efficiency of dynamic membranes is comparable to microfiltration and ultrafiltration membranes once the dynamic membrane is well formed. There are two basic types of dynamic membranes: pre-coated and self-forming. The pre-coated membrane is produced by passing a solution of one or more specific components over the surface of a porous support. The self-forming membrane is formed by the components in the solution to be filtered (Meng et al. 2009).

Biorefinery

Baoqiang Liao

Department of Chemical Engineering, Lakehead University, Thunder Bay, ON, Canada

A biorefinery is a facility that integrates biomass conversion processes and equipment to produce fuels, power, heat, and value-added chemicals from biomass (NREL web site 2014). The biorefinery concept is analogous to today's petroleum refineries, which produce multiple fuels and products from petroleum (NREL web site 2014). Raw materials for biorefinery are renewable lignocellulosic biomass, which include agricultural residues, wood residues, food wastes, grass, sugarcane, algal biomass, etc. The products of biorefinery include various types of biochemicals (cellulose, hemicellulose, lignin, succinic acid, lactic acid, lipids, adipic acid, butanol, fatty alcohols and esters, ethyl acetate, glycols, etc.), biofuels (bioethanol, biogas, bio-oil), and electricity. There are three main technical pathways for biorefinery of lignocellulosic biomass: thermochemical conversion, physicochemical conversion, and biochemical conversion. Thermochemical conversion uses heat and catalysis to produce biofuels and bioproducts and includes combustion, gasification, pyrolysis, and liquefaction of biomass. Physicochemical conversion applies physical and chemical methods to produce biofuels and includes pressing/extraction and esterification. Biochemical conversion utilizes enzymes and/or microorganisms to convert lignocellulosic biomass into bioproducts and/or biofuels and includes hydrolysis and fermentation

and anaerobic digestion. A typical bioprocess for bioethanol production from lignocellulosic materials includes the following major steps: pretreatment, hydrolysis, fermentation, and product (bioethanol) purification (He et al. 2012). First, the lignocellulosic material is pretreated to remove lignin and hemicelluloses. The remaining cellulose is then hydrolyzed to produce sugars which are fermented to produce ethanol. Finally, the ethanol is recovered and purified for commercial application. Separation technologies play an important role in this biorefining process, including ion-exchange resins that have been used for the detoxification of fermentation hydrolyzates, distillation in the recovery of ethanol, and ethanol dehydration. Membrane separation has been utilized in various stages of this biorefining process, including concentration of bioethanol by using membrane bioreactors and the removal of water from ethanol solution (Abels et al. 2013). Basically, there are three generations of biofuels, based on the use of different lignocellulosic biomass. First-generation biofuels include bioalcohols, biodiesels, biogas, and biosyngas and are typically derived from sugar, starch, and vegetable oil (Demirbas 2011). Biofuels from agroforestry wastes including the stalks of wheat, corn, wood, and dedicated nonfood-based bioenergy feedstocks (e.g., *Miscanthus*, willow, and poplar) form the basis of the second-generation biofuels (Sims et al. 2010). Third (3rd)-generation biofuels are derived from algae (Costa and de Moraes 2011). The fast-growing rate and utilization of CO₂ as carbon source make microalgae a fascinating biomass for biodiesel production, due to the high lipid content in microalgae. Optimization of processes for effective and efficient biomass conversion for first-, second-, and third-generation biofuels and for true integration in a biorefinery will require appropriate separation technologies. Compared to other separation technologies, the low energy consumption, greater separation efficiency, reduced number of processing steps, and high quality of the final product are the main attractions of membrane

separation processes in biorefining and bioenergy production (de Morais Coutinho et al. 2009).

Biorefinery with Membrane Operations

Baoqiang Liao

Department of Chemical Engineering, Lakehead University, Thunder Bay, ON, Canada

Membrane separations have been widely used in various stages of biorefinery, including upstreams for product manufacturing and downstreams for product purification. Full-scale biorefinery with membrane operations includes wastewater biorefinery for bioenergy recovery using anaerobic membrane bioreactors (AnMBR), dehydration of bio-ethanol using membrane separations, and lignin separation in integrated forest biorefinery.

In wastewater biorefinery, the potential energy stored in the organic compounds can be recovered as bioenergy (methane or hydrogen) through anaerobic digestion. One successful example of

membrane technology in wastewater biorefinery is the development of AnMBR technology. AnMBR is an integration of membrane separation with anaerobic digestion technology for bioenergy recovery. The use of membrane completely retains the slow-growing methanogens and eliminates biomass separation problems. To reduce energy usage, biogas sparging is used for membrane fouling control. AnMBR has the advantages of small footprint, high productivity, superior effluent quality for water reuse, and system closure. AnMBR has been successfully used for food processing wastewater treatment (Christian et al. 2010) and alcohol stillage wastewater treatment (Grant et al. 2008) for bioenergy recovery in full-scale plants. This indicates the successful application of membrane technology in the production of first-generation biofuel (biogas). The AnMBR technology achieved a high chemical oxygen demand removal (>98 % and 99.4 %) and bioenergy recovery in food processing wastewater and distilled wastewater treatment.

In the production of bio-ethanol, the first- and second-generation of biofuel, membrane separation technology has been successfully applied to concentrate bio-ethanol from fermentation broth and replace distillation for dehydration of bio-ethanol to save energy. In bio-ethanol production, the membrane is incorporated with the fermenters to create a membrane bioreactor for biomass separation and bio-ethanol concentration (Abels et al. 2013). To produce high-purity bio-ethanol (>99.5 %), pervaporation has been successfully used for dehydration of bio-ethanol (Oliverio et al. 2010). The principle of membrane dehydration of bio-ethanol involves two steps: molecules diffuse through the membrane as permeate and vaporization of the permeate into vapor phase through vacuum. The membrane system can be directly integrated in the rectification of existing ethanol plants or new ethanol systems. In doing so the energy demand of the complete ethanol system is minimized by arranging an optimized equipment configuration and strict heat integration. Both polymeric and ceramic membranes are used for bio-ethanol dehydration.

Full-scale membrane dehydration plants have been in operations all over the world. Thirty-five to 70 % reduction in energy consumption was observed in the downstream of bio-ethanol production, as compared to the distillation processes (Oliverio et al. 2010).

In integrated forest biorefinery, membrane filter has been used for lignin recovery from black liquor in kraft pulp mills. The lignin recovery process includes CO₂ precipitation, lignin separation, acid washing, and product drying. In a pilot testing in lignin precipitation and filtration, a LAROX filter equipped with a filter cloth from Tamfelt (S-2108-L1) was used to separate lignin from the aqueous solution after coagulation (Kouisni and Paleologou 2010). A filtration rate of 50–60 kg/m².h was achieved with no black liquor pretreatment (oxidation). After pretreatment (oxidation) of black liquor, the filtration rate was increased to 150–180 kg/m².h (Kouisni and Paleologou 2010). A LignoBoost™ commercial lignin plant with a production capacity of 70 tons lignin/day has been in operation in Domtar in Plymouth, NC, USA, since 2013 (Mitchell 2013). Another new full-scale lignin plant using the LignoForce™ technology is being built in Alberta, Canada.

A variety of compounds are classified as refractory when they are poorly biodegraded and/or exhibit a low value for the ratio of biological oxygen demand to chemical oxygen demand (BOD/COD) (Frimmel et al. 2008; Kopinke et al. 2002). These compounds are resistant or difficult to biodegrade, are toxic or are inhibitory to bacterial growth, and present an increasing problem in water and wastewater treatment systems (Delay et al. 2015).

These compounds could be organic (halogenated organics, aromatic and aliphatic hydrocarbons, pesticides, pharmaceutical products) or inorganic (metals, nanoparticles). Their origin could be anthropogenic or natural.

Membranes for biosensors

A biosensor is an analytical device used for the quantitative and qualitative detection of a specific analyte. A biosensor broadly consists of three main components: the biological sensing element which specifically interacts with the analyte, the transducer which is used to convert the signal from the bioelement-analyte interaction into a signal which is readable and reportable by the third component, the reading device (Fig. 1).

Membrane-based biosensors operate by reporting changes in ionic conduction through a

molecular membrane. These membranes consist of one or more lipid bilayer membranes, mimicking cell walls, upon a conducting (often gold) substrate (Cornell 2002). Many schemes have been reported for modulating the membrane ion conduction in response to the presence of a specific target analyte. The most common membrane-based biosensor was introduced by Cornell et al. where a mobile biological ion channel, initially gramicidin A, is tethered to an antibody of interest (Cornell et al. 1997). Under standard conditions, the ion channel is mobile throughout the membrane and predominantly exists in a dimer arrangement with a substrate-immobilized ion channel. Upon introduction of the target analyte, the analyte binds to both an immobilized antibody and the antibody tethered to the ion channel resulting in a conformational change of the ion channels, reducing conductance through the membrane (Cornell et al. 1997; Cornell 2002). From the change in conductance, a quantitative value of the amount of analyte present can be calculated. Membrane biosensors are promising for a range of diagnostic studies as the lipid membrane environment is ideal for the long-term storage of biological sensing elements (Oh et al. 2008).

Biosurfactant

Frederico de Araujo Kronemberger
COPPE – Chemical Engineering Program,
Federal University of Rio de Janeiro (UFRJ), Rio
de Janeiro, RJ, Brazil

A biosurfactant (also called microbial surfactant) can be defined as a surfactant compound produced by microorganisms. Since surfactants are amphiphilic compounds, presenting both hydrophilic and hydrophobic moieties, they tend to move toward the interfaces, reducing the surface and/or interfacial tensions. These properties make surfactants excellent detergency, emulsifier, foaming, and dispersing agents (Mukherjee and Das 2010). Biosurfactants can be categorized mainly by their chemical composition and their microbial origin, being classified as glycolipids, lipopeptides and lipoproteins, phospholipids and fatty acids, polymeric surfactants, and particulate surfactants, and they are produced by a great variety of microorganisms, either secreted extracellularly or attached to parts of cells (Desai and Banat 1997). The biosurfactants have several advantages over chemically synthesized surfactants such as lower toxicity, higher biodegradability, and effectiveness at extreme temperatures or

pH values, besides presenting high surface activity and low critical micelle concentration values emerging as promising substitutes of the latter (Vaz et al. 2012).

Concerning the oil industry, biosurfactants can be used in the bioremediation of oil pollutants, in the enhanced oil recovery (reducing the capillary forces that retain the oil in the reservoir rock), in the treatment of oily sludges, and in the cleanup of storage tanks. They can also be applied in the pharmaceutical (due to their antimicrobial activity) and agricultural sectors (for the hydrophilization of heavy soil), as a pesticide, and in the food industry (Mukherjee and Das 2010; Banat 1995; Freire et al. 2009). They can also be used in the effluent treatment, for metal ion removal from aqueous solutions (Ramani et al. 2012) and to enhance the water/oil interaction in the degradation of high fat content effluents (Damasceno et al. 2012).

Regarding membrane separation processes, biosurfactants can be used in the micellar enhanced ultrafiltration, in which small contaminants, like heavy metal ions, are bound onto larger surfactant micelle complexes. These ions associated with surfactant macromolecules can be easily retained by an ultrafiltration membrane module. El Zeftawy and Mulligan (2011) investigated the use of rhamnolipid biosurfactants (glycolipids) in the micellar enhanced ultrafiltration of cadmium, copper, nickel, lead, and zinc ions with polysulfone hollow-fiber ultrafiltration membranes with molecular weight cutoff of 10,000 and 30,000. The authors reported nearly complete rejection of the ions, considering a feed concentration of 5 mg.L⁻¹, when using a rhamnolipid solution above its critical micelle concentration with both membranes. Even when increasing the metal ion content up to 50 mg.L⁻¹, the biosurfactant concentration could be adjusted to enable their complete rejection, with a permeate flux up to 200 L.h⁻¹.m⁻².bar⁻¹. Hong et al. (1998) also reported the ultrafiltration of copper, zinc, cadmium, and nickel ions using a polycarboxylic acid-type biosurfactant. The author used flat-sheet cellulose acetate membranes with molecular weight cutoff of 1,000 and 3,000, but the biosurfactant was not as

effective as the rhamnolipid reported by El Zeftawy and Mulligan (2011), leading to lower rejection values.

Another interesting application of biosurfactant was reported by Qin et al. (2012). These authors used rhamnolipid biosurfactants to enhance the frying oil degradation and to reduce the membrane fouling in a submerged membrane bioreactor, and an increase from 66 % up to 91 % in the oil removal efficiency was reported. The antifouling property of the biosurfactant was also confirmed.

Besides, the biosurfactants could be used to replace their chemically synthesized counterparts in several other membrane processes, like the micellar enhanced ultrafiltration of aromatic alcohols and in the emulsion liquid membranes, used to remove and/or purify metal ions, dyes, lignosulfonate, and lactic acid.

A biosurfactant can be defined as a surfactant compound produced by microorganisms. The biosurfactants have several advantages over chemically synthesized surfactants such as lower toxicity, higher biodegradability, and effectiveness at extreme temperatures or pH values, besides presenting high-surface activity and low-critical micelle concentration values emerging as promising substitutes of the latter (Vaz et al. 2012). In the present moment, the biosurfactants still present high production costs in comparison to the chemically synthesized surfactants. That is mainly the result of the low productivity of the microbial strains and the inefficient methodology of the bioprocessing. The technological improvement of the production process is essential (Kronemberger et al. 2008). In order to decrease the production costs, the scale-up of the whole production process, including upstream and downstream, should be developed.

One of the bottlenecks of the biosurfactant production relies on the fact that most of them are obtained through aerobic bioreactions. The use of the conventional submerged aeration can lead to the formation of very stable foams, causing serious operational problems. In order to

overcome that difficulty, a nondispersive oxygenation process using membrane contactors can be applied (Kronemberger et al. 2008, 2012; Gruber and Chmiel 1991). Kronemberger et al. (2008) investigated the rhamnolipid-type biosurfactant production in bioreactors with a nondispersive oxygenation device, obtaining productivities higher to the ones observed in shake flasks. This system was then successfully used in a fed-batch experiment, in order to assess the potential of a long-term production (Kronemberger et al. 2010). Coutte et al. (2010) reported a similar system for the production of lipopeptide biosurfactants, comparing internal and external nondispersive oxygenation.

Several authors have been investigating the recovery of biosurfactants, mainly surfactin, using ultrafiltration. Chen et al. (2008a) reported the flux decline in the ultrafiltration of surfactin using cellulose ester and polyethersulfone membranes with 100,000 Da of molecular weight cut-off, and the latter was recommended as the best one for this kind of experiment, even though the biosurfactant recovery was a little lower. Isa et al. (2007) investigated a two-step ultrafiltration recovery system for surfactin. In the first step ultrafiltration, surfactin was retained by polyethersulfone or regenerated cellulose membranes at above its critical micelle concentration. In the second step, with the same kind of membranes, after the disruption of the micelles by the addition of methanol, the purified surfactin was recovered in the permeate. Chen et al. (2008b) also reported the surfactin recovery, but using ammonium sulfate salting out, ultrafiltration, nanofiltration, and their hybrid process. The combination of salting out and ultrafiltration was selected due to the reduction of the fouling in the membranes used.

Another point of view should be the whole integrated production system supported by membrane processes. A system described by Coutte et al. (2013) comprises the nondispersive oxygenation of a bioreactor for the production of surfactin and the continuous cell removal and product separation using microfiltration and ultrafiltration modules, respectively. A pilot scale system, designed for the production of rhamnolipid-type

biosurfactants, with 200 L of useful volume was also described (Kronemberger et al. 2012). It comprises microfiltration modules for fresh medium sterilization, nondispersive oxygenation, another set of microfiltration modules with self-backwashing for cell retention, and a reverse osmosis unit used to concentrate the product and to recover the water as the permeate stream, enabling its reuse and minimizing the effluents.

Biotechnology Processes Coupled with Membrane Separation

► Membrane Biotechnology

Biphasic Biocatalytic Membrane Reactors

Lidietta Giorno

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Synonyms

Multiphase enzyme membrane reactors; Two-separate phase biocatalytic membrane reactors

A schematic representation of a biphasic membrane is reported in Fig. 1. The system is suitable for bioconversions of low water soluble substrates. The enzyme loaded-membrane separates two immiscible phases: the substrate is present in the organic phase whilst the product is extracted in the aqueous phase. Particularly interesting is the

case where the biocatalyst is enantiospecific and converts only one of the substrate isomers giving in one step the production and separation of enantiomers in the optically pure form. The most studied enzyme in this systems are lipases. They are phase transfer catalysts activated by interface. When lipase is randomly loaded within the membrane and the two phases contact at a certain level of the porous thickness, only part of the lipase is located at the interface, whilst most of it is either in the water or in the organic phase (Fig. 2a). This results in an apparent lower activity of the immobilized enzyme.

An advanced development of multiphase reactor systems (emulsion enzyme membrane reactor) has been reported where the organic/water interface within the pores at the enzyme level is achieved by stable oil-in-water emulsion, prepared by membrane emulsification, so that each pore can work as a microreactor containing immobilized enzyme. In this way, the enzyme works in the membrane pores in the same conditions as in the stirred tank reactor, but with no shear stress due to stirring. Various configurations can be obtained. In one case the enzyme is immobilized within the porous matrix and the emulsion is fed to the membrane and pressed to pass through the enzyme-loaded membrane (Giorno et al. 2003). As long as the reaction rate

balances the convective transport rate there is no significant influence of fouling. Emulsion enzyme membrane reactors can also be prepared by immobilizing the emulsion and the enzyme within the porous structure of the membrane thickness, so that to have a two separate phase enzyme-emulsion loaded membrane, as illustrated in Fig. 2b (Giorno et al. 2007). This latter configuration guarantees a high enantioselectivity of phase transfer catalysts activated by interface, thanks to the fact that all immobilized enzyme is located at the oil/water interface.

These configuration improved the selectivity and productivity of the biocatalytic system as well as its catalytic stability.

A comparison between performance of different membrane materials used in multiphase enzyme membrane reactors is reported in Table 1.

Blending Modification of Membranes

Annarosa Gugliuzza

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

When using the word “blend,” we mean a mixture of two or more components with low or high molecular weight, organic or inorganic nature, and solid or liquid state. Physical or chemical blends with various degree of complexity can be produced depending on the nature of the mixed materials. Generally, in a blend we distinguish between a continuous film (*hosting matrix*) and a dispersed phase (*filler*) consisting of polymers, oligomers, nanoparticles, nanotubes, nanowires, zeolites, and so many others (Fig. 1).

The blending is used for making new formulations with superior performance, when components with complementary functions are well interlaced and uniformly distributed. Major concerns are compatibility, uniformity, adhesion, and minimum loading for maximum surface area (Gugliuzza 2013; Gugliuzza et al. 2006). Segregation, nano-confinement, phase separation, and

discontinuity are frequent phenomena, which take place in solution or during fabrication of the composite (Gugliuzza et al. 2007; De Lorenzo et al. 2012). These events occur mainly when the mixed compounds do not exhibit compatibility and/or miscibility at all. In this respect, the glass transition temperature (T_g) could be a powerful tool for examining the degree of miscibility of binary blends, e.g., mixed polymers. When one T_g is obtained, the blend is considered fully miscible. If two T_g values are measured and a dependence on the composition is estimated, the blend is partially miscible. Finally, immiscible blends show distinct and independent T_g values, as illustrated by Fig. 2.

A set of equations can be useful to predict the x -dependence of T_g , where x is the composition. The Fox equation (1956) is the simplest one and is traditionally used for binary systems, thereby giving indication based on the properties of pure components:

$$\frac{1}{T_g} = \frac{x_1}{T_{g1}} + \frac{x_2}{T_{g2}} \quad (1)$$

where T_g is related to the blend, whereas T_{gi} and x_i are glass transition temperature and composition of the i -esimo pure component, respectively.

Blending Modification of Membranes, Fig. 1 Examples of miscible and immiscible blends

Blending Modification of Membranes, Fig. 2 A schematic representation of the dependence of T_g on composition in binary polymer blends

The Gordon and Taylor equation (1952) includes an additional experimental parameter (k_{GT}) that considers unequal contributions of the components:

$$T_g = \frac{x_1 T_{g1} + k_{GT} x_2 T_{g2}}{x_1 + k_{GT} x_2} \quad (2)$$

Two other more complex relations are the Kwei (1984) and Brostow (2008), Eqs. 3 and 4, which take in account additional parameters such as K_{KW} , q , and a_i upon complexity of the polymer blend and/or copolymers:

$$T_g = \frac{x_1 T_{g1} + k_{KW} x_2 T_{g2}}{x_1 + k_{KW} x_2} q x_1 x_2 \quad (3)$$

$$T_g = x_1 T_{g1} + x_2 T_{g2} + x_1 x_2 \left[a_0 + a_1 (2x_1 - 1) + a_2 (2x_1 - 1)^2 + a_3 (2x_1 - 1)^3 \right] \quad (4)$$

In all equations the index 2 is referred to the component with the highest T_g , whereas x_2 is $1 - x_1$.

A good blend depends on the degree of interaction between the hosting matrix and the external surface area of the dispersed phase and can be

regarded as the result of the buoyancy of van der Waals forces and/or hydrogen bonds established at their interface (De Luca et al. 2009). Chemical functionalization and/or compatibilizing agents are two viable routes for strengthening these reciprocal interactions and dispersing the phases in continuous volumetric spaces. This needs to promote desired events in every region of the blend.

In membranes, the blend is a common practice to reinforce or produce specific properties, including transport, wetting, pores and mechanics, and so many others. Transport properties can be modified depending on the phase behavior and related morphology. Permeability, selectivity, or conductivity can be varied with respect to the upper bound relationship as a function of the orientation of the dispersed phase and/or the nature of the interface generated between the various components (Robeson 2010). Indeed, the molecular separation can be addressed via diffusion or sorption events dependently on free volume distribution and/or binding sites density.

Similarly, the blending can give new solutions to dry-wet membranes; changes in supramolecular chemistry can modulate the wettability, making the membrane usable for numerous times without damages and/or special treatments.

This approach is also preferred when pores must be generated through polymer networks. Pore-forming agents are often blended with polymers and, then, removed by washing treatments. This takes the advantage of generating empty spaces inside dense polymer networks, but the major difficulty is often the complete removal of the filler from the matrix. In this respect, a good compatibility between pore-forming agent and polymer matrix is necessary to produce a large number of uniform and regular pores through the network.

Finally, the blend is often preferred to provide composites with mechanical, chemical, and thermal properties beyond those observable for the single elements. Enhanced tensile properties along with reinforced resistance to high temperatures and harsh environments can be obtained by blending organic and inorganic materials in different ratios.

Composites and Biomaterials (IPCB-CNR),
Pozzuoli, Naples, Italy

Block Copolymers

Block copolymers are polymeric materials in which macromolecules of two or more different homopolymers (blocks) are chemically bonded together to form complex macromolecules with linear (di-, tri-, multiblock copolymers) or nonlinear (mixed arm star, block, or graft copolymers) architecture (Fig. 1).

The routes of synthesis of block copolymers are two:

1. Creating centers or active sites (radical, anionic, cationic) of a polymer chain that can subsequently trigger the polymerization of a second monomer. If the location of the terminal active center is not specified, this definition also includes graft copolymers.
2. Condensation between functional groups located at the end of the polymer or prepolymer:

If the species are bifunctional, multiblock copolymers can be obtained. Despite the general indications just described, the interest for the production of block copolymers is focused on anionic initiators and polymerization processes having living character. This way, derived from the original studies of M. Szwarc (1956), provides

Block Copolymer Membrane, Fig. 1 Linear and nonlinear architecture of block copolymers

copolymer sequences well defined, with desired molecular weights, structures, and compositions. All this is achieved with diene monomers, vinyl (nonpolar), esters, ethers, or cyclic sulfides.

The key technologies for producing block copolymers with anionic initiators can be indicated schematically in the following way:

- Sequential polymerization of the monomers (especially in the case of di-blocks)
- Polymerization of the second monomer with the functionalized prepolymers of the first monomer
- Use of reactions of coupling between reactive terminals and a compound reagent that becomes the junction site:

- Use of bifunctional initiators

The synthesis of multiblock copolymers can be obtained by an alternately sequential addition of different comonomers into a living copolymerization system or, alternatively, by the coupling of difunctional homopolymeric precursors.

In the first case, anionic polymerization or, more recently, living radical polymerization methods can be in principle used. In real cases (Ekizoglou and Hadjichristidis 2002; Buzdugan et al. 2000; Reuter et al. 1991), each addition of a

new monomer will inevitably make some living chains dead because of impurities, leading to the resultant block copolymer with lower block numbers and broad molecular weight distribution. Therefore, the sequential addition method can only be used to make copolymers with a few blocks, such as triblock copolymers. Another limitation of the sequential addition of different comonomers is their reaction compatibility: each added monomer must be sufficiently reactive so that the chain can propagate. Often, a living A block can initiate comonomer B, but a living B block cannot initiate comonomer A.

In the second approach, multiblock copolymers could be in principle prepared by coupling (Yagci and Tasdelen 2006) different polymer chain di-ends terminated with suitable reactive groups or by linking (Yagci and Tasdelen 2006; Rahman et al. 2007) di-end-functionalized polymer chains using so-called difunctional linking agents in solution. However, both coupling and linking reactions are extremely ineffective when long polymer chains ($M_w > 5 \times 10^3$) are used as the precursors because most of the reactive end groups are segregated inside the polymer chains coiled in good solvent. Moreover, for long polymer chains, the concentration of the reactive end groups is too low to have an effective coupling or linking reaction because the overall polymer concentration cannot be too high. Therefore, the essential problem is how to expose and

concentrate the reactive end groups of long polymer chains, while the overall polymer concentration will not be increased.

Block Copolymers in Membranes

Copolymers, and in particular block copolymers (BCPs), in recent years have aroused great interest in the field of specialty polymer applications, including nanotechnologies (Park et al. 2003; Krausch and Magerle 2002; Hamley 2003; Lazzari and Lopez-Quintela 2003; Lu and Sastry 2007; Hawker and Russell 2005; Li et al. 2005; Segalman 2005; Cheng et al. 2006; Stoykovich and Nealey 2006; Krishnamoorthy et al. 2006; Li and Ober 2006; Fasolka and Mayes 2001; Darling 2007; Kim and Hinsberg 2008; Bates and Fredrickson 1999; Abetz and Simon 2005; van Zoelen and ten Brinke 2009), given their ability to self-organize into structures with periodicity down to the nanometer scale.

If the different polymer blocks are chemically incompatible, phase separation occurs with spontaneous segregation of different macromolecules in different microdomains (Fig. 2). Microdomains formed are not arranged in a random but show a regular arrangement which involves the formation of periodic structures.

This phenomenon, called “self-assembly,” determines the spontaneous formation of nanostructures. It is associated with the competition between the tendency to separation of phase, due to the incompatibility of the blocks, and chemical connectivity that prevents it; periodic

structures are formed in which the contact area between the incompatible microdomains is minimized. The minimization of the interfacial area between the domains involves a reduction in interfacial energy for which even if from an entropic point of view the individual polymer chains prefer a conformation random coil, in the case of block copolymers, macromolecules tend to assume more extended conformations at the interface between the two blocks so as to allow similar blocks to organize into microstructures that minimize the ratio (surface exposed/volume).

The frequency and size of these domains depend on the lengths of the regular blocks and, therefore, from the molecular masses.

Block copolymers find many interesting applications in membrane technology.

Block copolymers have found application in a class of rubbery membranes, having the unique ability to separate CO₂ from gas streams, with a consequent increase in performance compared to that of the analogous homopolymers (Guan and De Simone 1994).

The polyethylene oxide [PEO] is, for example, one of the most interesting materials for the separation of CO₂, especially when cross-linked with other polymers or incorporated into block copolymers (Lin et al. 2006; Pethe et al. 2008). Because of its amorphous character and of its flexibility, it suitably directs the permselectivity of CO₂ through the polymer matrices, especially when the length of the segment, the weight, and the molecular ratio with the other blocks of the copolymer complexes are changed.

Block Copolymer Membrane,

Fig. 2 Schematic of “self-assembly” in BCPs due to phase separation

Bondar et al. (2000) observed that the permeability of CO₂ increases with the amount of polyether [PEO or PTMEO] when segmented block copolymers are incorporated into the polyether-*b*-polyamide, where they form the segregated phase of nylon-6 [PA6] or nylon-12 [PA12]. In particular, they have observed that the copolymers 57PEO/PA6 and 55PEO/PA12 exhibit a better selectivity to pure gas CO₂/N₂ 56 (PCO₂ 66 barrer) and CO₂/H₂ 9.8 (PCO₂ 20 barrer), respectively, compared to more conventional polymers rubbery and glassy.

Higher performance was observed when more than one unit polar (PEO and PA6) were included in the polymer chain, suggesting the critical role of interesting polar intermolecular interactions between the polymer chain and the penetrating molecules. Membranes PEO/PBT have been ad hoc designed in order to obtain block copolymers with high performance for the separation of CO₂ (Zhao et al. 2008). Separation factors for the pairs of gases, such as CO₂/H₂, CO₂/N₂, and CO₂/CH₄, were obtained in different ratios of the polymer chain. When mixed with the polyether glycol [PEG], a significant improvement of the permeability and selectivity for various block copolymers was observed.

Blood Cell Origins

A. Higuchi

Department of Chemical and Materials Engineering, National Central University, Chung-Li, Taoyuan, Taiwan

Blood cell origins are from the hematopoietic stem cells (HSCs). HSCs can generate all types of the blood cells such as the erythrocytes (red blood cells), lymphocytes (T cells, B cells, and NK (natural killer) cells), monocytes, macrophages, neutrophils, basophils, eosinophils, megakaryocytes/platelets, and dendritic cells. HSCs are found in the bone marrow of adults, which includes the femurs, hip, ribs, sternum, and other bones. Cells can be obtained from the iliac crest part of the pelvic bone, using a special needle and a syringe; the cells removed are of two forms, i.e., as a smear and as a core biopsy. HSCs can be also found in the umbilical cord blood (UCB, 15–75/ml) and peripheral blood (1/ml). The low number of HSCs and small volume (50–150 ml) obtainable from a single donor of UCB limit direct transplantation of UCB to the treatment of pediatric patients. A density of 1.7×10^7 CD34⁺ cells (HSCs)/kg is necessary for the transplantation of UCB into patients (Higuchi et al. 2010). Therefore, UCB transplantation has been limited to children with an average weight of 20 kg. Numerous efforts have been made to expand HSCs ex vivo to improve

engraftment time and reduce the graft failure rate, particularly in developing this therapy for adult patients (Higuchi et al. 2010). HSCs cultured in 2D materials and in porous membranes can be possible to expand ex vivo.

Ex vivo expansion of HSCs is a hot topic due to the shortage of HSCs in clinical application. HSCs can be defined by surface marker of cells such as CD (cluster of differentiation). The cells of CD34⁺CD45[−] or CD34⁺CD38[−] are generally believed as HSCs, which are measured from flow cytometry where “+” indicates the expressing cells and “−” indicates non-expressing cells. CD133⁺CD34[−] cells are believed as more progenitor HSCs than CD34⁺CD38[−] cells.

Efficient cell separation is an important issue for the successful isolation and purification of HSCs. Centrifugation, affinity column chromatography, fluorescence-activated cell sorting (FACS), magnetic cell selection (MACS), and membrane filtration are techniques typically employed for cell separation (Higuchi et al. 2009). Highly purified cellular preparations are obtained using Ficoll–Paque method followed by FACS or MACS in conjunction with a fluorescently labeled antibody as the cell surface marker, while the cell separation by membrane filtration method is less specific, but is simple and easy operation, and sterility can maintain during the process. Only half an hour is necessary to purify HSCs from the blood by the membrane filtration method, while the conventional Ficoll–Paque followed by MACS method needs around 8 h (Higuchi et al. 2009) (Fig. 1).

Blood Cell Origins,

Fig. 1 HSCs are blood cell origins, which are multipotent stem cells giving rise to all of the blood cell types

Blood Filtration

A. Higuchi

Department of Chemical and Materials Engineering, National Central University, Chung-Li, Taoyuan, Taiwan

Blood filtration is performed by hemodialysis membranes, leukocyte removal filter, and plasma separation membranes.

Blood is composed of plasma solution and blood cells. Several valuable proteins such as immunoglobulin, factor VIII, factor IX, albumin, vitronectin, etc. are contained in plasma solution. Blood cells are erythrocytes (RBC, red blood cells), lymphocytes (T cells, B cells, and NK (natural killer) cells), monocytes, macrophages, neutrophils, basophils, eosinophils, megakaryocytes/platelets and dendritic cells, and hematopoietic stem cells (HSCs). HSCs are found in the bone marrow of adults, which includes femurs, hip, ribs, sternum, and other bones.

In hemodialysis, the patient's blood is pumped through the blood compartment of a dialyzer, exposing it to a dialysis membrane. The dialyzer is composed of thousands of tiny synthetic hollow fibers. The fiber wall acts as the semipermeable membrane. Blood flows through the fibers, dialysis solution flows around the outside of the fibers, and water and wastes move between these two solutions. The cleansed blood is then returned via the circuit back to the body. Ultrafiltration occurs by increasing the hydrostatic pressure across the dialyzer membrane. This usually is

done by applying a negative pressure to the dialysate compartment of the dialyzer. This pressure gradient causes water and dissolved solutes to move from blood to dialysate and allows the removal of several liters of excess fluid during a typical 3- to 5-h treatment. Hemodialysis treatments are typically given in a dialysis center three times per week.

Hemodialysis membranes are typically prepared from cellulose materials or polysulfone-polyvinylpyrrolidone (PVP)-blended materials. Cellulose is hydrophilic and can be used as a hemocompatible material, whereas polysulfone is one of engineering plastics and needs to add a hydrophilic and hemocompatible material as a blending material. PVP shows relatively good hemocompatibility, and a more important fact is that PVP can be blended well with polysulfone. PVP is also used as a porogen in dialysis membranes of polysulfone. There is a recent demand for hemodialysis membranes that remove the low molecular weight proteins such as β_2 -myoglobin (MW 11500) and endotoxin (subunit of MW = 5,000–20,000), and useful albumin in the plasma should be recovered by the membranes. Polysulfone hollow fibers blended with PVP have been widely used as suitable hemodialysis membranes which satisfy this requirement (Higuchi et al. 2002).

Leukocyte removal filter: White blood cells (leukocytes) generate many adverse reactions during blood-transfusion therapy, which are graft-versus-host disease (GVHD), platelet refractoriness, nonhemolytic febrile transfusion reaction, and infection of viruses, such as human T-lymphotropic virus (HTLV), cytomegalovirus (CMV), and human immunodeficiency virus (HIV) (Higuchi 2010). It was found that most of the viruses infect specific type of leukocytes, such as granulocytes, monocytes, lymphocytes, B lymphocytes, T-helper cell ($CD4^+$ cell), and suppressor/cytotoxic T cells ($CD8^+$ cell) (Higuchi 2010). Therefore, removal of leukocytes in RBC and platelet concentrates as well as whole blood components is essential to prevent the adverse effect of contaminated leukocytes. Leukocytes can be removed using a filter comprised of nonwoven fabric or sponge materials as a filter

medium. The mechanism of leukocyte removal on the filters comprised of nonwoven fabric is based on the adsorption of leukocytes, while that comprised of sponge materials is based on the sieving effect and adsorption.

Plasma separation membrane: Plasma-exchange therapy has been increasingly applied clinically over the past few years. Membrane plasma separation has been used since 1979, which is similar to hemodialysis and hemofiltration. Plasma separation from whole blood is now performed routinely.

The materials of plasma separation membranes are typically made of nitrocellulose, polysulfone, and polypropylene.

Blood Separation

A. Higuchi
Department of Chemical and Materials
Engineering, National Central University,
Chung-Li, Taoyuan, Taiwan

Blood separation can be performed by centrifugation, magnetic cell selection system (MACS), fluorescence-activated cell sorting (FACS), and membrane filtration method. Blood is a living

tissue composed of several blood cells in plasma. The cellular elements of red blood cells (RBCs), platelets, and white blood cells make up 45 % of the volume of whole blood. Another 55 % is plasma, which contains 7–8 % of the plasma proteins and 92–93 % of water (Higuchi 2010). Figure 1 shows typical blood after centrifugation with and without addition of Ficoll-Paque (Ficoll-Hypaque) solution. After centrifugation of blood without addition of Ficoll-Paque (Ficoll-Hypaque) solution (native blood centrifugation), blood can be separated into plasma layer, platelet and leukocyte layer, and RBC layer (Fig. 1a). In this case, each layer contains other contaminant cells, e.g., RBC layer contains 96 % of RBCs, 3 % of leukocytes, and 1 % of platelets in blood cells. Platelets and leukocytes are also included in plasma layers. Platelet-rich plasma is necessary to use for the evaluation of biocompatibility of biomaterials (Higuchi et al. 2003). Platelet-rich plasma is obtained by centrifugation of peripheral blood or umbilical cord blood at 3,000 rpm. Platelet-poor plasma is used for plasma protein adsorption on biomaterials for the evaluation of biocompatibility of the biomaterials (Higuchi et al. 2003). Platelet-poor plasma is obtained by centrifugation of peripheral blood or umbilical cord blood at a relatively high speed of 3,000 rpm. Mononuclear cells including hematopoietic stem cells (HSCs) cannot easily be obtained by centrifugation of native blood. Therefore, Ficoll-Paque (or Ficoll-Hypaque) solution was injected into blood sample, and the mixed solution was centrifuged at $400\times g$ for 30–40 min at 20 °C (Fig. 1b). The upper layer contains plasma and platelets. Mononuclear cells including lymphocytes (T cells, B cells, and NK (natural killer) cells) and HSCs can be isolated from the upper second layer (Fig. 1b). When specific cells such as HSCs, T cells, N cells, or NK cells should be isolated, MACS or FACS are applied. Direct application of MACS and FACS to isolate the specific blood cells is difficult due to large quantity of RBCs in blood samples. After the mononuclear cells were isolated by Ficoll-Paque method, residual RBCs were removed by the treatment of lysing solution and then HSCs (CD34⁺ cells) can be isolated by MACS or FACS

Blood Separation,

Fig. 1 Blood components after centrifugation of native blood (a) and before and after centrifugation of blood with Ficoll-Paque solution (b)

Blood Separation,

Fig. 2 Schematic mechanism of the separation method of cells by a magnetic cell selection system

treatment using antibody of CD34⁺ (Chen et al. 2012).

MACS is a sophisticated cell separation method, in which magnetic beads attaching a monoclonal antibody as the cell-surface marker are mixed with cells. Figure 2 shows the schematic mechanism of the separation method by an

MACS. The magnetic beads attaching the monoclonal antibody are separated by magnetic force to collect the specific marked cells. The MACS needs to use an expensive antibody conjugated with magnetic beads to bind to the target cells for the detection of the cells. Both cell separation methods using FACS and MACS are not

applicable if the antibodies to the specific markers on the surface of the target cells have not been established.

Blood cell separation through membrane filtration was recently reported by several researchers (Komai et al. 1998; Yasutake et al. 2001; Higuchi et al. 2004, 2008). Typical blood cell separation membranes are leukocyte removal filter (membrane) and HSC purification membranes.

HSC separation from peripheral blood and umbilical cord blood through surface-modified polyurethane membranes by membrane filtration method was reported (Higuchi et al. 2004, 2008, 2010). Peripheral blood or umbilical cord blood was permeated through the surface-modified membranes by filtration. HSCs are more adhesive cells than RBCs, platelets, and lymphocytes. Therefore, HSCs remained to adhere on the membranes during permeation of blood. The membrane-adhering HSCs were rinsed with phosphate buffer saline and subsequently human serum albumin or dextran solution as surfactant solution was permeated through the membranes. The HSCs can be harvested in the recovery solution of human serum albumin or dextran solution. The membrane filtration method of blood separation should be useful, because centrifugation instrument is not necessary to use and antibodies targeting specific cells are not used in the method, which cause contamination of antibodies in the blood cell samples.

Blood Treatment Membrane

A. Higuchi
Department of Chemical and Materials
Engineering, National Central University,
Chung-Li, Taoyuan, Taiwan

Blood treatment membrane is categorized as dialysis membrane, leucocyte removal filter, and plasma separation membrane.

Dialysis Membrane

Dialysis is a process for removing waste and excess water from the blood and is used primarily to provide an artificial replacement for lost kidney function in people with renal failure. Dialysis was used for those with an acute disturbance in kidney function (acute kidney injury), or progressive but chronically worsening kidney function.

Dialysis works on the principles of the diffusion of solutes and ultrafiltration of fluid across a semipermeable membrane. Blood flows by one side of a semipermeable membrane, and a special dialysis fluid flows by the opposite side. A semipermeable membrane (dialysis membrane, dialyzer) is a thin layer of material that contains the appropriate size of pores. Smaller solutes (urea, NaCl) and fluid pass through the membrane, but the membrane blocks the passage of larger substances such as red blood cells and large proteins (albumin, globulin). This is the filtering process taking place in the kidneys, when the blood enters the kidneys and the larger substances are separated from the smaller ones in the glomerulus (Daugirdas et al. 2006).

In hemodialysis, the patient's blood is pumped through the blood compartment of a dialyzer, exposing it to a dialysis membrane. The dialyzer is composed of thousands of tiny synthetic hollow fibers. The fiber wall acts as the semipermeable membrane. Blood flows through the fibers, dialysis solution flows around the outside of the fibers, and water and wastes move between these two solutions (Daugirdas et al. 2006). The cleansed blood is then returned via the circuit back to the body. Ultrafiltration occurs by increasing the hydrostatic pressure across the dialyzer membrane. This usually is done by applying a negative pressure to the dialysate compartment of the dialyzer. This pressure gradient causes water and dissolved solutes to move from blood to dialysate and allows the removal of several liters of excess fluid during a typical 3- to 5-h treatment. Hemodialysis treatments are typically given in a dialysis center three times per week (Daugirdas et al. 2006).

Hemodialysis membranes are typically prepared from cellulose materials or polysulfone-polyvinylpyrrolidone (PVP)-blended materials. Cellulose is hydrophilic and can be used as a hemocompatible material, whereas polysulfone is one of the engineering plastics and needs to add a hydrophilic and hemocompatible material as a blending material. PVP shows relatively good hemocompatibility and the more important fact is that PVP can be blended well with polysulfone. There are a lot of materials reported excellent

biocompatibility. However, these biocompatible materials cannot be used as blending materials in polysulfone dialysis membranes due to low mixing with polysulfone. PVP is also used as a porogen in dialysis membranes of polysulfone. There is a recent demand for hemodialysis membranes that remove the low-molecular-weight proteins such as β_2 -myoglobin (MW 11,500) and endotoxin (subunit of MW = 5,000–20,000) and useful albumin in the plasma should be recovered by the membranes. Polysulfone hollow fibers blended with PVP have been widely used as suitable hemodialysis membranes which satisfy this requirement (Higuchi et al. 2002).

Leukocyte Removal Filter

White blood cells (leukocytes) generate many adverse reactions during blood-transfusion therapy, which are graft-versus-host disease (GVHD), platelet refractoriness, nonhemolytic febrile transfusion reaction, and infection of viruses, such as human T-lymphotropic virus (HTLV), cytomegalovirus (CMV), and human immunodeficient virus (HIV) (Higuchi 2010). It was found that most of the viruses infect specific type of leukocytes, such as granulocytes, monocytes, lymphocytes, lymphocytes-B, T helper cell (CD4⁺ cell), and T-cell suppressor/cytotoxic cells (CD8⁺ cell). HTLV-1 and HIV mainly infect T helper cell, while CMV mainly infects granulocytes, monocytes, and lymphocytes. GVHD was mainly generated by T helper cell and T-cell suppressor/cytotoxic cells (CD8⁺ cell) (Higuchi 2010). Therefore, removal of leukocytes in RBC and platelet concentrates as well as whole blood component are essential to prevent the adverse effect of contaminated leukocytes. Leukocytes can be removed using a filter comprised of nonwoven fabric or sponge materials as a filter medium. The mechanism of leukocyte removal on the filters comprised of nonwoven fabric is based on the adsorption of leukocytes, while that comprised of sponge materials is based on the sieving effect and adsorption.

Filtration methods have several advantages compared to other methods of removing

leukocytes such as centrifugation. Virus contamination is lower in blood components during the process in the filtration method than in the centrifugation method due to mild operation and the ease of operation under sterilized conditions.

Leukocyte removal filters were typically made of polyurethane (PU) foaming membranes where the pore was made by salt leaching method and nonwoven fabric. The pore structure of both filters is found to be completely different, although the pore size of those filters was almost the same from capillary flow porometer measurements. The mechanism of leukocyte removal (i.e., separation of leukocyte from plasma and other blood cells) in leukocyte removal filters is based on leukocyte adsorption on the filters. The adsorption of leukocytes was affected significantly by filter materials, pore structure, and pore size.

Plasma Separation Membrane

Plasma-exchange therapy has been increasingly applied clinically over the past few years. Membrane plasma separation has been used since 1979, which is similar to hemodialysis and hemofiltration. Plasma separation from whole blood is now performed routinely. The materials of plasma separation membranes are typically made of nitrocellulose, polysulfone, and polypropylene.

Blowdown Water

Aamer Ali

Department of Environmental and Chemical Engineering, University of Calabria, Rende, Italy

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Operational principle of steam and water boilers, cooling towers, evaporative coolers, and evaporative condensers is based upon the evaporation of water. Dehydration from these equipment leaves behind a solution enriched with nonvolatile substances mainly including salts of calcium, magnesium, sodium, and silica, requiring the discharge of contaminant-rich water. The drained volume of water in order to maintain an acceptable level of impurities in the evaporation equipment is known as blowdown water or bleed water or simply blowdown. In addition to the salts, blowdown water can also contain bacteria, algae, and pathogens. Increased concentration of minerals and other impurities is undesirable for several applications. For example, in steam boiler, the evaporation of pure water can lead toward the scale formation, water carryover with steam, and blockage of the piping system, while in case of cooling tower, concentrated blowdowns cause scaling and corrosion problems even in downstream equipment. The concentration of salts and other solid species in blowdown water is much higher than the original feedwater introduced.

In boiler, the blowdown water is discharged from the surface and bottom to get rid of floating and settled impurities, respectively. On one side, less amount of blowdown water may cause the

scale formation, water carryover, local heating leading toward the failure of boiler tubes, and less heat exchange rate, while the excessive discharge of blowdown water leads toward increased water usage, loss of energy associated with the discarded steam, large amount of makeup water, and excessive use of chemicals. Therefore, the quantity of blowdown water must be optimized.

Scarceness of freshwater, stringent environment regulations, and cost reduction are the driving forces for treatment of blowdown water. State-of-the-art treatment techniques for cooling tower blowdown water include lime-soda softening and thermal evaporation. The former removes hardness but involves the use of chemicals and produces sludge. Thermal evaporation, on the other hand, is highly energy intensive. Due to environmental concern, the concept of zero liquid discharge for treatment of blowdown water has gained popularity recently. The main tools to achieve zero liquid discharge under consideration include membrane filtration, electrodialysis, and evaporation.

In boilers, chemical pretreatment is applied to reduce the scaling problem and to enhance the heat transfer rate. These chemicals along with the other contaminants present into the boiler feedwater form sludge that settles down at the bottom of the boiler. Consequently, the blowdown becomes richer in impurities. Alternative membrane-based pretreatment can be applied to tackle these problems. For example, ultrafiltration has been used to affectively remove colloidal silica from the feedwater that imparts a vigorous effect in controlling the boiler blowdown (Kochi membrane systems, Inc. 2004). A more refined membrane process such as nanofiltration or reverse osmosis can further improve the consequence.

As far as the posttreatment of boiler blowdown is concerned, there have not been significant efforts devoted, probably due to high concentration and very complex nature of the waste stream. However, advanced membrane operations, especially membrane distillation, can be appropriate candidate due to high temperature and concentration of the stream and less fouling tendency of the MD process (Yu et al. 2013). In case of cooling tower, where the objective is to recover water with

quality equal or higher than that of makeup water, various membrane operations have been tested. Nanofiltration and reverse osmosis have shown the capability to treat the water to required purity level but usually require a pretreatment step. On the other hand, forward osmosis and membrane distillation have shown more interesting results in terms of less severe pretreatment requirements, operational stability, and less fouling problems.

Introduction

The energy crisis is becoming one of the most pervasive problems facing the world today plagued with rapid economic growth and exponential increase in the global population. The key solution is sustainable energy that combines renewable energy with high energy efficiency to balance the growing energy needs without jeopardizing the earth's climate. Of great interest is the potential of

“blue energy” associated with osmotic power that can be harvested from the salinity gradient between two water streams such as seawater and freshwater, as seawater is globally distributed (Lewis et al. 2011), available all day and all year round. Two emerging membrane techniques, pressure retarded osmosis (PRO) and reverse electrodialysis (RED), are the primary methods proposed for recovering the osmotic energy.

PRO Working Principles

Three osmotic processes are illustrated in Fig. 1:

- Reverse osmosis (RO) that utilizes hydraulic pressure (ΔP) to overcome the osmotic pressure gradient ($\Delta\pi$) across a semipermeable membrane ($\Delta P > \Delta\pi$), leading to the net water movement from the concentrated feed (F) to the permeate (P) side.
- Pressure retarded osmosis (PRO) that applies a hydraulic pressure lower than the osmotic pressure gradient to the high-salinity stream (draw solution (DS)) ($\Delta P < \Delta\pi$), giving a net water flux in the direction toward the draw solution.
- Forward osmosis (FO) that uses the osmotic pressure gradient as the driving force without

hydraulic pressure ($\Delta P = 0$). Water flows from a less concentrated feed (F) to a more concentrated draw solution (DS).

PRO is an intermediate osmotic process between RO and FO. As long as the osmotic pressure difference across the semipermeable membrane is greater than the applied pressure on a high-salinity stream, water will continuously flow from a low-salinity stream at a low pressure into the pressurized high-salinity stream. The increased volume of pressurized water is able to drive a turbine for power generation (Thorsen et al. 2009), resulting in the recovery of the chemical potential energy from the difference in osmotic pressures of the two water streams, as shown schematically in Fig. 2.

RED Working Principles

Unlike PRO, RED primarily depends on ion transport through the membranes when waters of different salinities are placed on opposite sides of either cation or anion exchange membranes. These membranes are stacked in an alternating pattern between a cathode (reduction electrode) and an anode (oxidation electrode) (Post et al. 2007). Another distinctive difference is that

Blue Energy,

Fig. 1 Osmotic processes using semipermeable membranes: (a) RO; (b) PRO; (c) FO (arrow indicates the direction of water flow)

Blue Energy,

Fig. 2 Schematic of PRO process for power generation

Blue Energy, Fig. 3 A simple RED process showing the transport of ions where *A* is an anion exchange membrane and *C* is a cation exchange membrane

the RED system is not pressurized like PRO to obtain the osmotic energy mechanically. Instead, direct electrical energy can be harvested from the movement of the electrons required to maintain electroneutrality of the overall solution as the ions from the saline solution are transported toward either the anode or cathode electrodes, as shown schematically in Fig. 3.

Specifically, electroneutrality is maintained via reduction at the cathode and oxidation at the anode via an external electric circuit that results in electrons being transferred from the anode to the cathode. Electrical energy can then be harnessed directly when an external load is connected to the circuit through the electrical current (movement of electrons) and the potential difference over the electrodes. Although the applied electrical potential difference will reduce the driving force of the ions when the external load is connected to the circuit, ions will continue to be transported toward the cathode and anode as long as the electrochemical potential difference is greater than the electrical potential difference.

Challenges and Potential Large-Scale Applications

The PRO process requires a robust membrane that can withstand high-operating pressures and achieve a reasonable high water flux (Chou

et al. 2012), while RED requires not only a membrane of minimal electrical resistance but also the whole stack design with a low electrical resistance. Normally, seawater and freshwater are used as a pair for both PRO (Lewis et al. 2011; Thorsen et al. 2009; Ramon et al. 2011) and RED (Ramon et al. 2011; Długołęcki et al. 2010) processes to harvest salinity gradient energy. Other salinity gradient pairs such as concentrated brine from seawater desalination (Enomoto et al. 2010) or hypersaline lakes such as the Dead Sea (Loeb 1976, 2001; Lacey 1980) are also possible resources for utilization. It is expected that large-scale applications for PRO and RED would be near river estuaries, hypersaline lakes, or seawater desalination plants. In particular, the co-location of PRO/RED with seawater desalination plants would allow the recovered energy from the RO brines to be used to desalinate the water.

In the oil and gas and mining industries, large amounts of water streams with high total dissolved salts (TDS) are produced from the hydraulic methods used in the harvesting of gas from coal beds (McBeth et al. 2003), oil from subsurface formation (Ahmadun et al. 2009), or from mining activities (Balaba and Smart 2012). Thus, the recovery of osmotic energy from such produced water streams is also possible for large-scale applications.

Bore Liquid: Solvent and Nonsolvent

Khayet Mohamed

Department of Applied Physics, Universidad Complutense de Madrid, Madrid, Spain

B

Bore injection liquid is an internal coagulant pumped through the inner tube of the spinneret used for fabrication of hollow fibers by the dry/wet spinning technique or the wet spinning technique. Figure 1 shows schematic illustrations of the cross-sections of the spinneret used in these techniques. The spinneret has a tube-in-orifice structure with typical dimensions 0.5–1 mm inner diameter and 0.9–2 mm outer diameter.

The bore liquid is one of the controlling parameters of the wet spinning and dry/wet spinning techniques used to fabricate hollow fibers. It must be a non-solvent or a non-solvent mixture exhibiting a low affinity with the polymer solution

Bore Liquid: Solvent and Nonsolvent, Fig. 1 Transversal (a) and lateral (b) cross-sections of a common spinneret used in dry/wet spinning and wet spinning techniques

(dope solution). The solubility parameter of the bore liquid must be different from that of the polymer to be coagulated. The interactions between solvent and coagulant and between solvent and polymer play important roles affecting the rate of polymer precipitation (coagulation, solidification). For poly(vinylidene fluoride) (PVDF) polymer solution as an example, water is a strong coagulant commonly used for fabrication of hollow fibers. In the dry/wet spinning or wet spinning, the polymer solution under gas pressure is extruded from the annular space of the spinneret, whereas the internal coagulant (bore liquid) is driven through the central tube of the spinneret either by gravity force or by means of a circulation pump. Coagulation of the internal surface of the nascent fiber starts immediately after its extrusion from the spinneret, whereas the external surface experiences coalescence, and orientation of polymer aggregates through the air gap before gelation in the external coagulation (i.e., non-solvent or non-solvent mixture) bath. The air gap is the vertical distance between the spinneret and the liquid coagulation bath and it may vary from 0 (wet spinning) to more than 1 m (dry/wet spinning). The bore liquid and the solvent exchange by diffusion and then the polymer solution become thermodynamically unstable. Demixing may take place from the bore side or lumen side and from the shell or outside of the as-spun fiber. Two types of demixing are possible: liquid–liquid demixing and gelation or crystallization. Gelation is not a phase separation process whereas crystallization involves a solid–liquid demixing. In order to determine the composition or temperature at which the solution is no longer thermodynamically stable, turbidity or cloud points must be determined. Cloud points are defined as the moment when the solution changes from clear to turbid. To localize the cloud point of a ternary system, a possible method is titration of polymer solution containing polymer and solvent with non-solvent or with a mixture of solvent and non-solvent at a given temperature until permanent turbidity is detected. The turbidity point can be detected by turbidity measurements or light scattering methods.

When a strong bore liquid coagulant such as water for PVDF polymer is used for the fabrication of a hollow fiber membrane, a dense and smooth surface with no obvious pores is formed. However, when a weaker coagulant is employed such as methanol, which may be mixed with water, the roughness of the internal surface of the formed hollow fiber may increase considerably due partially to the formation of pores. Figure 2 shows the effects of the bore liquid coagulant on the cross-sectional structure of porous hydrophobic hollow fibers prepared by the dry/wet spinning technique (Khayet et al. 2002). Water and 50 % (by volume) ethanol in water were used as internal and external coagulants. Different cross-sectional structures can be observed. In Fig. 2a prepared with water as internal and external coagulants, long finger-like voids are formed near the inner surface, while smaller cavities are formed near the outer surface. Between the inner and outer layers, sponge-like structure appears. The inner layer is reduced when ethanol is added to the internal coagulant as can be seen in Fig. 2b. A uniform sponge-like structure extends over the entire hollow fiber cross-section, in Fig. 2c, when ethanol is added to both the internal and external coagulants. The addition of ethanol delays the coagulation process, and a long finger-like structure changes to a short finger-like structure and further to a sponge-like structure. The slow coagulation of the hollow fibers can be explained on the basis of the mutual diffusivity of solvent/non-solvent exchange and solubility parameters of the materials involved in hollow fiber spinning. The addition of ethanol in water reduces the diffusion of non-solvent into the nascent hollow fiber and consequently decreases the rate of precipitation (coagulation, precipitation). The surface roughness increased when ethanol was added to the bore liquid coagulant, which is due to the increase of the pore size. The pores at the inner surfaces of the hollow fibers are larger than those at the outer surfaces, and the pore size increases both at the inner and at the outer surfaces as ethanol was added to the coagulants (Khayet et al. 2002). A decrease of the porosity of PVDF hollow fibers was also observed with the addition of ethanol in the bore liquid.

Bore Liquid: Solvent and Nonsolvent, Fig. 2 Cross-sectional scanning electron microscopy (SEM) structure of PVDF hollow fiber membranes prepared by wet/dry spinning technique with different coagulants: (a) water

coagulant, (b) internal coagulant 50 % ethanol in water and external coagulant water, (c) 50 % ethanol in water coagulant (Reprinted from Khayet et al. (2002), Copyright 2002, with kind permission from Elsevier)

Boric Acid Separation by Membrane Contactor

Alessandra Criscuoli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Boron is usually found in water as boric acid, and its concentration ranges from few ppb in river

water up to around 7 ppm in seawater and can be even higher in wastewaters discharged from some industrial plants. Due to its toxic effects on both humans and plants, the World Health Organization (WHO) has fixed at 0.3 ppm the maximum allowed concentration of boron in water. Different are the techniques that can be used for controlling the boric acid content of water, like adsorption, ion-exchange resins, solvent extraction, electrodialysis, multiple stages of reverse osmosis units (working at different pH), and membrane contactors. In particular, the effectiveness of membrane contactors has been confirmed using various configurations to treat waters containing boric acid.

Boric acid was selectively separated through supported liquid membranes containing inside micropores 1,3-diols (carrier) dissolved into o-dichlorobenzene. The membranes were

Boric Acid Separation by Membrane Contactor,

Fig. 1 Transport of boric acid through a supported liquid membrane

Boric Acid Separation by Membrane Contactor,

Fig. 2 Transport of boric acid in a hydrophilic membrane

hydrophobic and separated the aqueous stream containing boric acid from an alkaline aqueous phase, representing the so-called receiving phase; see Fig. 1 (Bachelier et al. 1996).

The removal of boric acid was also obtained by employing hydrophilic microporous membranes, sending distilled water as extractant phase. In this case, the membrane pores were filled with the aqueous feed, and, by properly acting on the pressures of the two phases, the interface was located at the membrane surface-extractant side, so that the boric acid removal occurred by simply diffusion from the feed to the extractant (Fig. 2). For practical implementations, an integrated membrane system where the extractant was continuously regenerated and recycled to the membrane contactor was also proposed and designed (Criscuoli et al. 2010a, b).

Successful performances of hydrophilic microporous membranes using distilled water as

extractant were also observed by Park and Lee (1995). Moreover, they found good efficiencies of anion exchange membrane contactors for the removal of boric acid from liquid radioactive wastes.

Boron Reduction

Piotr Dydo
Silesian University of Technology, Gliwice,
Poland

Synonyms

Boron removal

Characteristics

The boron element has an average concentration in the Earth's crust equal to about 10 mg/kg. Due to its strong affinity toward oxygen, it exists in nature mainly in the form of boric acids or borates. Boric acid and borates are mainly used in the glass and ceramic industry to obtain borosilicate glass, insulation fiberglass, flame retardant fiberglass, ceramic glazes, and porcelain enamels. Boron compounds are also used as a flame retardant in plastics and cellulosic insulation, neutron absorbers, herbicides (when at high concentrations) or fertilizers (when at low doses), and components of washing powders and soaps.

According to the WHO (2009) and (2011), average boron concentration in surface waters does not exceed the value of 0.5 mg/L. However, the amount of boron in these waters depends upon the presence of boron-bearing minerals in the proximity of water reservoirs. It may also be affected by the discharge of municipal and industrial effluents into the environment. On the other hand, naturally occurring boron is present in ground waters at a wide concentration range from <0.3 to >100 mg/L. This includes strongly mineralized, naturally carbonized geothermal waters. Considerable amounts of boron are also present in oceans, with an average concentration of 4.5 mg/L as reported by the WHO in 2009.

Despite the fact that boron is an important nutrient, it manifests toxic action against plants

and animals when found at high concentration in irrigation or drinking water. The effects of boron on plants and mammals were summarized by the WHO (2009), Kabay et al. (2010), and Hilal et al. (2011). Among the reported effects, the adverse impact of boron on the male reproductive system in rats, mice, and dogs was presented. Based on analysis of toxicokinetic of boron, the WHO proposed a guideline value for boron in drinking water of 2.4 mg/L in 2011. In areas with high natural boron levels, local regulatory and health authorities are, however, advised to consider values in excess of 2.4 mg/L by assessing exposure from other sources (e.g., food).

The low drinking water boron content limit implies the necessity for a reduction of boron content in drinking water, especially when seawater or boron-rich underground waters (e.g., geothermal waters) are to be treated. There could also be a need for boron removal from industrial and municipal effluents that contain more than the WHO guideline value. Conventional methods for water treatment do not significantly remove boron. The methods proven to be efficient in a reduction of boron content in waters are either adsorption or membrane based. Adsorption-based methods for boron removal include coagulation with metal hydroxides, adsorption on clays, fly ashes, and activated carbon (WHO 2009). Also, successful boron reduction with conventional anion exchange resins or resins functionalized with N-methyl D-glucamine (Chillon Arias et al. 2011) was reported. Among the membrane-based methods, boron removal by reverse osmosis is reported most commonly. Also some achievements in boron removal with ion-exchange membranes as well as boron removal by electrodialysis are presented. In addition, some hybrid systems, which combine membrane filtration with sorption, are proposed, e.g., the adsorption-membrane filtration (AMF) system. In this system, microparticulate boron selective resin suspension is recirculated in the retentate. Boron species remains adsorbed on the resin, while the boron-depleted water is continuously separated by microfiltration. According to

Kabay et al. 2008, the main advantage of the AMF over other methods of boron separation lies in the fast removal of boron, ease of sorbent separation, and low operating pressure.

According to the WHO (2009), the abovementioned methods for boron removal are likely to be prohibitively expensive, and blending with waters of low boron content may be the only economically feasible option to reduce high concentrations of boron in water.

Boron Removal by Electrodialysis

Piotr Dydo

Silesian University of Technology, Gliwice, Poland

As in the case of boron removal by reverse osmosis, the effectiveness of boron removal by electrodialysis (ED) is strongly affected by the aqueous chemistry of the boron species. In aqueous solutions, boric acid may exist in the form of boric acid, metaborate, and polyborates. Boric acid as a weak electrolyte ($pK_a = 9.2$) dominates in diluted aqueous solutions of a pH equal to or less than 9, while at higher pH borate ions dominate. Therefore, the effectiveness of boron transport across ion-exchange membranes (IEM) in the electrodialysis process needs to be discussed with regard to the type of the species that dominates in the dilute.

The Effectiveness of Boric Acid Transport in ED

Boric acid, H_3BO_3 , is a small and electrically neutral species. The reported boric acid removal efficiencies and electric current efficiencies in ED are poor when compared to ionic species (Melnik et al. 1999; Turek et al. 2005, 2007, 2008a; Kabay et al. 2008; Banasiak and Schafer 2009; WHO 2009). In fact, boric acid fluxes across IEMs are so low that the possibility of boric acid separation from ionic species, strong acids (Melnik et al. 2005, 2007) and salts (Turek et al. 2005, 2007; Bandura-Zalska et al. 2009; Dydo 2012a), by the use of electrodialysis is considered. Employing this method, ionic species are effectively transported across IEMs while boric acid remains in the ion-depleted dilute solution.

The type of the membrane, the dilute boron concentration, the presence of ions in the dilute, and the electric current density were shown to affect the rate of boric acid transport across IEM to a great extent (Melnik et al. 1999; Yazicigil and Oztekin 2006; Kabay et al. 2008; Dydo 2012a).

Boron Removal

- [Boron Reduction](#)

The reported mechanism for boric acid transport across IEMs is diffusion (Dydo 2012b); however, the flux of boric acid was found to increase with an increase in the flux of ionic species. This was suggested to be the result of a kind of ion-coupled transport of boric acid across IEMs. The effectiveness of such a transport was found to decrease in the following ion series: sulfate $\gg$ nitrate $\gg$ chloride. It was also reported that most of the boric acid was transported across anion-exchange membrane (AEM).

Turek et al. (2008b) reported high boron fluxes and exceptionally high electric current efficiencies of up to 220 % when boric acid was transported from ion-depleted, neutral or acidic, dilute into the alkaline concentrate of pH >11. Such a behavior was identified to be the result of Donnan dialysis, in which hydroxyl acts as a carrier for boric acid. However, in the light of recent reports, simple boric acid diffusion should explain the results as well.

Tentative results on boron removal by electrodialysis units equipped with ion-exchange spacers were also presented by Oren et al. in 2006. The possibility of up to an 80 % reduction of boron from water containing 4.5 mg/L was reported.

The Effectiveness of Borate Transport in ED

Melnik et al. (1999), Yazicigil et al. (2006), and Kabay et al. (2008) reported that as the pH of boron-containing water was brought up to just above the value of 9, a significant increase in the rate of boron transport across IEMs is observed. Moreover, Melnik et al. (1999) reported that in the case of heterogeneous membranes, an increase in the boron transport rate across anion-exchange membrane at pH >9 is accompanied by a decrease in the rate of boron transport across cation-exchange membrane (CEM). It is clear that under these conditions (pH >9), borates are the boron species that dominates and their transport across AEMs rather than CEMs should be discussed. The effectiveness of borate transport across AEMs in ED systems was found to depend

upon the pH of the dilute, the type of the membrane, dilute boron concentration, and the kind of the ion cotransported across the membrane. Yazicigil et al. in 2006 reported that at a dilute pH of approx. 9, there is a maximum boron transport rate, and at higher pH the rate of boron transport decreases. These results are contradictory to those presented by Melnik et al. (1999) (heterogeneous membranes), Turek et al. (2007), and Kabay et al. (2008), according to which there is a continuous increase in the rate of boron transport with dilute pH even when above 9.0. However, the Yazicigil et al. (2006) results seem to be justified by high boron concentration (0.1 mol/L) in their experiments. Similar behavior was observed by Ayyildiz and Kara in 2005. It is agreed that an increase in dilute boron concentration causes an increase in boron (borate) flux (Yazicigil et al. 2006; Kabay et al. 2008; Turek et al. 2008a). It is also agreed that boron (borate) is transported faster in the presence of chloride ions than in the presence of sulfates (Yazicigil et al. 2006; Kabay et al. 2008) or nitrates.

In 2005 and 2008a, Turek et al. analyzed the effect of salinity on the electric current efficiency of boron (borate) transport. They found that the observed electric current efficiencies are low as long as dilute salinity remains high. During the initial part of the experiments, no, or almost no, boron was transported from the dilute. Then, i.e., when more than 90 % of the Cl^- was removed from the dilute, a dramatic increase in boron (borate) electric current efficiency was observed. This increase was accompanied by an increase in boron flux. Such an effect can be identified as the result of low borate mobility (diffusivity) when compared to other ions present in the waters, i.e., Cl^- . As long as there are ions of higher mobility than borates in the dilute, boron (borate) flux remains low. However, even in an ion-depleted dilute, the electric current efficiency of boron (borate) transport has not exceeded the value of 30 %. The remaining percentage of the electric current was probably utilized for hydroxyl ion transport. A considerable drop in the pH of the dilute was reported afterwards. This resulted in a drop in dilute pH and in a consequent reduction in

the flux of boron since all the borate present was converted into boric acid. So the low electric current efficiency of borate transport in an ED system and the necessity for deep dilute demineralization make the economic feasibility of borate removal by ED questionable.

Boron Removal by Reverse Osmosis

Piotr Dydo
Silesian University of Technology, Gliwice,
Poland

Reverse osmosis (RO) is a commonly applied membrane technique of desalination capable of producing permeates of drinking-water quality. In most cases, the boron content in the product should not exceed the WHO 2009 and 2011 guideline value of 2.4 mg/L. The effectiveness of boron rejection by reverse osmosis membranes is, however, strongly affected by its concentration in the feedwater and the aqueous chemistry of boron specie (Kabay et al. 2010; Hilal et al. 2011). In aqueous solutions, boric acid may exist in the form of boric acid, metaborates, and polyborates. Boric acid as a weak electrolyte ($pK_a = 9.2$) dominates in diluted aqueous solutions of a pH less than 9. Since the pH of most naturally occurring waters is lower than 9, the rate of boric acid transport determines the effectiveness of boron removal by RO.

According to Kabay et al. 2010, the rejection of boric acid by RO membranes is, however, low due to its small size and lack of electric charge. The reported boron rejection coefficients range from around 20 % in the case of old RO membranes to approx. 90 % in the case of modern RO

membranes (WHO 2009; Kabay et al. 2010; Hilal et al. 2011).

The effectiveness of boron removal from seawater by RO can be enhanced by adjusting the feedwater pH to above the value of 9.25. The monoborate anion, which dominates in diluted solutions at $\text{pH} > 9.5$, was found to be rejected more effectively than boric acid due to its larger size and discrete charge (Kabay et al. 2010; Hilal et al. 2011). The reported boron rejection coefficients at $\text{pH} = 11$ exceeds 99 % in the case of dense seawater reverse osmosis membranes. Also, in the case of boron-rich geothermal waters and industrial wastewaters, high boron rejection is observed only at $\text{pH} > 10.5$ (Koseoglu et al. 2010; Dydo et al. 2005). Furthermore, it was shown that the effectiveness of boron removal can be further enhanced by creating borate complexes (esters) with polyhydroxyl alcohols (Geffen et al. 2006; Dydo et al. 2012), although again, under alkaline conditions only.

The results of mechanistic studies on boron rejection by reverse osmosis membranes conducted by Sagiv and Semiat (2004), Hyung and Kim (2006), Hun et al. (2009), and Tu et al. (2010) showed that permeabilities of boric acid are at least one order of magnitude larger than those of monoborate ion. It proves more intensive diffusion of boric acid than of borate across RO membranes. Also, the reflection coefficients for boric acid (<0.985) are considerably lower than those specific for monoborate (>0.995) as reported by Hyung and Kim (2006). This, in turn, indicates strong boric acid–water interaction.

Feedwater pH is said to have a dominant impact on boron rejection by RO membranes (Hilal et al. 2011). Among other RO parameters that affect boron rejection are: operating pressure (increase), feed temperature (decrease), feedwater salinity (decrease), and recovery (decrease).

However, RO systems cannot be directly operated at high feedwater pH due to the possibility of membrane scaling with insoluble calcium and magnesium basic compounds. Therefore, several modifications to the operation of RO and its design have been proposed. In general, a cascade design for RO systems in which a fraction of the first stage permeate is treated in the following RO

stages (if possible at elevated pH's) and a blending of all the permeates produces water of the desired quality (Hilal et al. 2011; Faigon and Hefer 2008). This design was successfully applied, e.g., in the full-scale seawater treatment plant in Eliat.

Boron Removal with Ion-Exchange Membranes

Piotr Dydo

Silesian University of Technology, Gliwice,
Poland

Apart from boron removal by electrodialysis, ion-exchange membranes are able to transport boron in the so-called Donnan dialysis (DD) or diffusion dialysis processes (Fig. 1).

Ayyildiz and Kara (2005) examined the effectiveness of boron transport across anion-exchange membranes in a DD process. They found that boron flux depends upon the membrane, concentration of boron in the feed solution, pH of the feed and receiving solution, presence of the

accompanying ions in the feed solution, and the type of the carrier anion in the receiving solutions. The effect of pH of the feed solution was found to be complex. At high boron concentration (0.1 mol/L), maximum boron flux was observed at around the pH of 9.5, while in the case of a diluted solution (0.001 mol/L), maximum boron flux was observed at the maximum examined feedwater pH of 11.5. Such behavior was explained by the formation of polyborate ions at high boron concentrations and their absence in diluted solutions. The maximum rate of boron transport at the pH of around 9.5 in the case of concentrated boron solution was later confirmed by Yazicigil et al. in 2006. Ayyildiz and Kara in 2005 reported also that the pH of the receiving phase affects boron flux with its maximum at around a pH of 9.5. Moreover, the boron-accompanying anions, chlorides, bicarbonates, and sulfates, were found to affect the rate of boron transport in DD with a maximum observed in the presence of bicarbonate. On the other hand, the highest boron transport rates were observed with sodium chloride in the receiving solution. Neosepta AHA and AMH membranes produced similar fluxes of boron, while the superiority of

Boron Removal with Ion-Exchange Membranes, Fig. 1 Boron Removal with Ion-Exchange Membranes

AFN was clearly seen. In 2011, Kir et al. showed that plasma modification of the existing anion-exchange membranes may result in a significant enhancement of the rate of boron transport in a DD process.

The mechanistic study on boric acid transport across cation-exchange membranes (CEMs) in a DD process was presented by Goli et al. in 2010. It was reported that the membrane diffusion coefficients for boric acid depend not only upon the manufacturer of the CEM but also upon the type of the cation present in the membrane. The same behavior is reported for arsenite. In general, in the presence of monovalent cations in the membrane, higher fluxes of boron were observed than in the presence of divalent cations. Such a behavior was later confirmed by Dydo in 2012. The existing differences in boric acid membrane diffusion coefficients were rationalized by Goli et al. (2010) as being the result of the change in the mean viscosity of the solution confined in membrane pores.

In 2007, Bryjak et al. proposed a Donnan dialysis-based method for the regeneration of finely divided boron selective resin (BSR) DOWEX XUS 43594.00. In this process, BSR slurry with boron adsorbed on it is fed into the DD feed compartment. It was assumed that there are always some minute amounts of borate in the feedwater at equilibrium with the BSR. These amounts were subject to transport into the receiving solution as a result of Donnan dialysis, which should ultimately result in complete boron removal from the BSR. The net effect of the process would be a regenerated resin in the chloride form and boron (borate)-rich receiving solution. As reported by Bryjak et al. (2007), considerably high boron fluxes were observed during the course of a DD regeneration of boron containing BSR. Boron desorption was found to be the phenomena that governs kinetics of the boron transport in the process.

Unfortunately the tentative, mostly mechanistic report on DD boron removal presented in this chapter does not provide much information about the effectiveness of boron removal from water nor its final concentration. It seems that a lot of work

needs to be done to enhance the kinetics of the diffusive transport of borate during DD.

Breakthrough Pressure

Renzo Di Felice

University of Genova, Genova, Italy

The pressure required for a liquid to enter the membrane pore is called breakthrough pressure. This parameter is of practical relevance as the membrane will not work properly if liquid enters the pores reducing in this way the contact efficiency. Breakthrough pressure can be estimated by using the Young-Laplace equation

$$P = \frac{-2\sigma \cos \theta}{r}$$

where σ is the liquid surface tension, θ the contact angle, and r the radius of membrane pore. It can be seen that high breakthrough pressure can be obtained by using liquids with high surface tension, by reducing the pore size, and by increasing the contact angle. However, there are practical limitations. For example, most of the physical solvents used for bulk CO₂ removal have low surface tensions, and the reduction in the membrane pore size beyond certain limit results into reduced transport of the gas through the membrane due to diffusion limitations. The higher contact angle for a given solvent is favored by the membrane material having low surface energies.

In order to give an idea, a hydrophobic polypropylene membrane with a pore size of 0.05 μm has a breakthrough pressure larger than 1 MPa (Wiesler 1996).

Buffer Displacement in Diafiltration

Greg Foley

School of Biotechnology, Dublin City University,
Dublin, Ireland

Buffer displacement involves the use of diafiltration to replace the solvent (non-product) fraction of a macromolecular solution, with a buffer. The basis of the operation is that the solvent, including low molecular weight impurities,

passes through the membrane, while the solute (product) is retained. Suppose the solution can be viewed as a mixture containing a macromolecular product, A, and a micromolecular impurity, B. Now suppose that the buffer contains a desired component, C – a salt perhaps. Then, buffer displacement involves the reduction in the concentration of B while keeping the concentration of A constant and raising the concentration of C to the desired level. This can be done using constant volume (continuous) diafiltration, discontinuous diafiltration by dilution, or discontinuous diafiltration by volume reduction.

If constant volume diafiltration is used and B has an apparent rejection coefficient of zero, the concentration of B declines according to the expression (Cheryan 1998)

$$c_B = c_{B0} \exp(-V_b/V_s)$$

where V_b is the volume of buffer added while V_s is the (constant) volume of solution. Assuming that component, C, also has a rejection coefficient of zero, its concentration in the retentate solution increases according to the expression

$$c_c = c_{c0}(1 - \exp(-V_b/V_s))$$

where c_{c0} is the concentration of C in the buffer tank. If the product, A, has a rejection coefficient of 1.0, its concentration will remain unchanged.

Buffer Flush in Diafiltration

Greg Foley

School of Biotechnology, Dublin City University,
Dublin, Ireland

A buffer flush is simply the replacement of an impure, product-containing solution with buffer by subjecting it to ► [diafiltration](#).

The most common way of performing a buffer flush, at least in a membrane context, is to use constant volume (continuous) diafiltration in which a certain volume of buffer is added to a given volume of impure solution while that solution undergoes batch ultrafiltration, all the while keeping the solution volume constant.

The greater the ratio of buffer volume (V_b) to solution volume (V_s) (► [Diafiltration Factor](#)), the greater will be the reduction in undesired impurities. For example, if an impurity has a rejection coefficient of 0.2 and the diafiltration factor is 5×, the reduction in impurity concentration is given by (Foley 2013)

$$c/c_0 = e^{-(1-\sigma)V_b/V_s} = e^{-5(1-0.2)} = 0.018$$

Bulk Biotech Industry

Frank Lipnizki
Alfa Laval Copenhagen, Søborg, Copenhagen,
Denmark

The term “bulk biotech industry” is referring to the use of biological processes on industrial scale to produce bulk products. Examples of products from the bulk biotech industry are antibiotics, enzymes, organic and amino acids, vitamins, bioalcohols, and biopolymers. One of the earliest biotechnological processes adopted by humans is the production of alcohol by fermenting fruits around 5000–6000 years ago. The production of lactic acid by Pasteur in 1857 is often considered to be the beginning of modern biotechnology followed by the industrial scale production of citric acid by Pfizer in 1923 (Chotani et al. 2007). The first wave of biotechnology started with the discovery of penicillin by Fleming

in 1928 paving the way for the industrial scale production of antibiotics and amino acids. The discovery and increased understanding of the DNA created the foundation to use molecular engineering to recombine DNA leading to the second wave of biotechnology processes in the 1980s. The current third and so far final wave of biotechnology – the white biotechnology – aims to replace the C_2/C_3 chemistry based on fossil fuels such as oil and gas by biotechnological processes. It is foreseen that in the near future, up to 20 % of all chemical products with a market value of approx 250 € billion will be produced by biotechnology. Approximately 60 % of the products produced by white biotechnology will be intermediated chemicals used in the pharmaceutical industry, and the remaining 40 % will be biopolymers and special chemicals for various industries (Festel et al. 2004).

Since the 1970s, cross-flow membrane processes have established themselves in the downstream processing of the biotechnology industry for the recovery and purification of the products. It is foreseen that membrane processes will also play an important role in white biotechnology and the related concept of biorefineries. Similar to petroleum refineries, biorefineries are aiming for the full utilization of biomass for the simultaneous production of biofuels, biochemicals, heat, and power (Axegård 2005). The integrated production of biomaterials can be based on, e.g., sugar, starch, and cellulose-based feedstock and as such extend current sugar, starch, and pulp factories. Membrane processes as highly selective and energy-saving processes are well suited to play an important part in biorefineries and thus the white biotechnology.

The key membrane technologies for the bulk biotech industry are microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO). Other membrane technologies such as membrane contactors (MC), electrodialysis (ED), pervaporation (PV), and vapor permeation (VP) plus membrane bioreactors for continuous fermentation are less established but have, nevertheless, the potential to become increasingly important.

Bulk Liquid Membrane

Vladimir S. Kislik

Campus Givat Ram, Casali Institute of Applied Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

Bulk liquid membrane (BLM) consists of a bulk aqueous feed and receiving phases separated by a bulk organic, water-immiscible liquid phase. The feed and receiving phases may be separating from the LM by microporous supports or may be without supports (layered BLM).

Many technologies that were developed and tested in the last two decades have to be included in the BLM group. These are hybrid liquid membrane (HLM), hollow-fiber liquid membrane (HFLM), hollow-fiber-contained liquid membrane (HFCLM), pertraction, flowing liquid membranes (FLM), membrane-based extraction and stripping, multimembrane hybrid system (MHS), and membrane contactor systems. All these systems are based on membrane-based nondispersive (as the means for blocking the organic reagent from mixing with the aqueous feed and strip solutions) selective extraction coupled to permselective diffusion of solute-extractant complexes and selective stripping of the solute in one continuous dynamic process (see Fig. 1). A great number of terms for similar bulk LM processes confuse the readers. The terms vary by membrane type used (hollow fiber, flat neutral, ion-exchange sheets) or by module design. All abovementioned bulk LM processes with

water-immiscible organic liquid membrane solutions may be unified under the term bulk organic hybrid liquid membrane (BOHLM) systems (for more details, see Kislik 2010a).

Bulk LM processes with water-soluble carriers are defined as bulk aqueous hybrid liquid membrane (BAHLM) systems (for more details, see Kislik 2010b). Regenerable water-soluble polyionic complexants are used as suitable aqueous liquid membrane carriers. These polyelectrolytes typically have a very high effective concentration of charged groups and could constitute highly selective complexants. The BAHLM technology is based on a combination of liquid membrane (LM) process and dialysis (D) in the case of neutral hydrophilic membranes or Donnan dialysis (DD) in the case of ion-exchange membranes used.

BOHLM and BAHLM technologies achieve the necessary transport and selectivity characteristics to have potential for commercial applications. Applications of the BOHLM processes are mainly in metal separation, wastewater treatment, biotechnologies, drugs recovery-separation, organic compounds, and gas separation. Selective separations of alkali, alkali earth, rare earth, heavy metal ions, precious metals, etc., are studied by many authors using all above-described techniques. Recovery and separation of carboxylic and amino acids from fermentation broth have been tested using layered BLM, rotating, creeping, spiral-type FLM, HFLM, HLM, and MHS-PV techniques of the BOHLM processes. Separation of ethylene, benzene, propanol, olefin, and aromatic amines from organic liquid mixtures and of volatile organic compounds (VOC) and phenol from wastewater was investigated using a rotating film module, spiral-type FLM, and hollow-fiber and layered LM techniques. High separation factors ($>1,000$) in pilot- and industrial-scale experiments were found. In the last two decades, BOHLM techniques were intensively used in analytical chemistry for separation and preconcentration of metals, organic acids, organic, and pharmaceutical compounds.

BAHLM is a new technology and few studies are known up to date. In metal separations copper-cadmium recovery from chloride aqueous solutions and cadmium, copper, and zinc separation

Bulk Liquid Membrane, Fig. 1 Schematic transport models of a bulk organic hybrid liquid membrane (BOHLM) system with **a, d** hydrophobic membranes and **b, e** hydrophilic or ion-exchange membranes

from wet-process phosphoric acid are studied. BAHLM systems were tested for the separation of carboxylic acids such as lactic, citric, and acetic or their anions. Continuous separation of different isomeric mixtures of organic compounds has been studied by means of a hollow-fiber-contained liquid membrane, HFCLM.

In recent years, integrated hybrid systems incorporating two or more functions in one module, for example, biotransformation and separation, become of great interest to researchers. The BOHLM systems, integrating reaction, separation, and concentration functions in one apparatus (bioreactor) attracted great interest in the last few years. Bioreactors combine the use of specific biocatalyst for the desired chemical reactions, with repeated or continuous application of it under very specific conditions. Such techniques were termed hybrid membrane reactors.

Butanol-Water Mixtures: Separation by Pervaporation

Wanqin Jin

State Key Laboratory of Materials-Oriented Chemical Engineering, Nanjing University of Technology, Nanjing, China

Because of the shortage of crude oil and the environmental requirement, the utilization of renewable resources for energy production, such as using the potential acetone-butanol-ethanol (ABE) fermentation process to produce butanol as a biofuel, has been receiving increased attention in recent years. However, the fermentation

process suffers from severe inhibition due to the high toxicity of butanol to microorganisms even at low concentrations ($4\text{--}6\text{ g}\cdot\text{L}^{-1}$). In order to eliminate the inhibition, in situ product recovery systems have been developed (Vane 2005). Pervaporation (PV) is considered to be a particularly promising recovery technique, because of its general advantages in energy saving and environmental issue, particularly no medium ingredients removed from the fermentation broth and no harmful effects on microorganisms.

The hydrophobic pervaporation membranes used for butanol recovery and concentrate include: polydimethylsiloxane (PDMS) and its modified copolymer and mixed matrix membranes, liquid membrane, poly[1-(trimethylsilyl)-1-propyne] (PTMSP) membrane, poly(ether block amide) (PEBA) membrane, polypropylene (PP) membrane, polytetrafluoroethylene (PTFE) membrane, etc. (Vane 2005; Liu et al. 2011). PDMS, as the most typical hydrophobic polymeric membrane, is widely investigated and proved to be stable and prospective for industrial applications. The operating parameters of PV, including feed temperature (T), feed concentration (C), feed flow rate and permeate pressure (P), etc., have significant impacts on membrane performance. Take the PDMS/ceramic membrane, for example, flux increased as temperature increased, while the separation factor decreased slightly. As the butanol concentration increased, the total flux increased while the separation factor changed slightly. The total flux increased with the flow rate, but the separation factor changed little (Liu et al. 2011).

Pervaporation using hydrophobic membranes might not be enough for concentrating butanol for direct reuse. Hydrophobic membranes were preferred for concentrating butanol when the

concentration of butanol is low. As an alternative, when the butanol concentration is high and the water content is low, the hydrophilic membranes should be used for the water removal, so that the pervaporation process is economic for butanol production.

The hydrophilic pervaporation polymeric membranes used for dehydration of butanol-water mixtures include: poly (vinyl alcohol) (PVA) membrane, polyimide membrane, chitosan membrane, sodium alginate membrane, polyelectrolyte, etc. (Chapman et al. 2008). PVA is the most commonly used hydrophilic polymeric membrane, but it often shows a lack of chemical, mechanical, and thermal stability. In recent years, the PI membrane began to be used for dehydration because of its excellent mechanical and thermal stability. The main inorganic membranes used for butanol dehydration are silica membrane (Verkerk et al. 2001) and A-type zeolite (NaA) membrane (Morigami et al. 2001).

Cadmium Separation by Liquid Membranes

Naser Dalali

Phase Separation and FIA Lab, Department of Chemistry, Faculty of Science, University of Zanjan, Zanjan, Iran

Cadmium separation by liquid membranes:

Cadmium occurs as a minor component in the zinc ores. It has many common industrial applications. Despite wide applications, cadmium is known to be a toxic element, and the occupational exposure is by inhalation of fumes and ingestion of soluble cadmium compounds. This metal is an environmental hazard. Therefore, due to its industrial, chemical, or environmental importance, it must be separated prior to determination or recovery from original matrices. Liquid membranes broadly classified into bulk, emulsion, and supported liquid membranes (SLM) have found wide applications for separation of metal species (including cadmium) during the recent years (Dalali et al. 2012; Kumbasar 2008; Carletto

et al. 2009). Bulk liquid membranes (BLM) usually consist of two aqueous feed and stripping phases, separated by a water-immiscible liquid membrane phase with a relatively small surface area. Emulsion liquid membranes have a very high surface area per unit of volume and low thickness. The problem is that the vehicles have to be produced before the process; they have to be stable enough to have minimum leakage, but still not very stable so that they could be destroyed after the separation. In SLM, usually organic liquid is imbedded in small pores of a polymer support and is kept there by capillary forces. If the organic liquid is immiscible with the aqueous feed and strip streams, SLM can be used to separate the two aqueous phases.

Hollow fiber modules are usually more expensive, but they offer much higher surface area per unit of module volume. In the simplest case, the organic solvent with a carrier is filling the pores of the microporous walls of hollow tubes. Transport with liquid membranes is a kinetic process and controlled by diffusion rate of analyte through the membrane. The membrane separation processes operate at ambient temperature and thus use less energy than thermal separations. The basic concept for a metal cation to transport through a liquid membrane (regardless of membrane type) is its conversion to (i) an uncharged hydrophobic species in the feed-membrane phase interface and (ii) a hydrophilic species in the

membrane-stripping phase interface. Therefore, the metal ion should either form an ion pair complex or a chelate in the presence of a hydrophobic organic salt or chelating agent as carrier in the membrane phase to fulfill such requirement. On the other hand, the selectivity of transport or separation efficiency depends upon the stability of metal complexes (ionic or neutral) or salts formed in feed, membrane, and stripping phases, which in turn is affected by the type and concentration of salt in the two aqueous phases and of carrier (extractant) in membrane phase. The separation of cadmium by a BLM as a chloride complex via its ion pair formation with trioctyl methyl ammonium chloride (Aliquat 336) in benzene as organic carrier into EDTA solution as stripping phase (Dalali 2012) was influenced by concentration of NaCl in the feed phase, concentration of carrier (Aliquat 336), and type and concentration of stripping solution (EDTA). The rate of transport depends upon the area and thickness of membrane or the interfaces. The larger the surface area and the less the thickness of interface, the faster will be the mass transfer. The effective separation of cadmium is achieved in the above, e.g., within 4 h, while the similar separation by an ELM has been achieved within 10 min time (Kumbasar 2008), due to the larger surface area and the thinner interface in ELM.

[Cadmium rejection by NF](#); [Cadmium wastewater treatment by NF](#)

Heavy metals present in wastewaters cause serious problems to human beings and other living organisms. Different methods are available to separate heavy metals such as precipitation, coagulation, flocculation, ion exchange, electro-dialysis, reverse osmosis (RO), nanofiltration, etc. (Wang et al. 2007). Nanofiltration (NF) is relatively new and it falls between RO and ultra-filtration (UF). NF can be operated at much lower pressures than RO. NF can achieve high removal of divalent and multivalent ions, but only moderate removal of monovalent ions is possible (Wang et al. 2006). Nanofiltration can be characterized by molecular weight cutoff (MWCO) between 200 and 1000 due to the pore diameter range of 0.5–2 nm, and also NF membranes are either positively charged or negatively charged. NF permits the retention of small molecules in the molecular mass range of 200–2000 Da (Wang et al. 2011). Cadmium is mainly toxic to the kidney and can also cause bone demineralization. Cadmium is one of the endocrine disruptor compounds (WHO 2013). The International Agency for Research on Cancer (IARC) has classified cadmium as a human carcinogen (Group 1) on the basis of occupational studies (European Food Safety Authority 2009). Cadmium is an odorless, silver-white, blue-tinged malleable metal or grayish-white powder with an oxidative state of +2, and it forms salts such as sulfate and nitrate. In the environment, cadmium is not usually present as a pure metal but as a mineral, such as cadmium oxide, cadmium chloride, cadmium sulfate, cadmium sulfide, etc. The chlorides and sulfates are

most easily dissolved in water. Cadmium metal itself does not disappear from the environment, but it may change forms; hence, knowing the particular form of cadmium is very important when determining the risk of potential adverse health effects (US Department of Health and Human Services, July 1999). When RO and NF are compared in separating cadmium from wastewater, the results showed that RO was capable of treating wastewater with an initial concentration of 500 ppm and reducing the ions concentration to about 3 ppm (99.4 % removal), whereas the average removal efficiency by NF was 97 % (Qdais and Moussa 2004). Cadmium separation from wastewaters by NF assumes importance due to its low-energy consumption and ease of operation. By using an NF-300 membrane system (Murthy and Chaudhari 2008, 2009; Chaudhari and Murthy 2010), the separation of cadmium from dilute aqueous solutions having different cadmium salts was reported. In wastewaters generally cadmium is not alone but is present with other metals such as nickel. Separation data were reported for CdCl₂-water system, CdCl₂-NiCl₂-water system, CdSO₄-NiSO₄-water system, and CdCl₂-NiSO₄-water system (Murthy and Chaudhari 2008, 2009; Chaudhari and Murthy 2010). The separation capability of an NF membrane can be related with its reflection coefficient. If reflection coefficient is zero, it means the separation of a solute is zero, and similarly if it is one, the separation is 100 %. Table 1 (Murthy and Chaudhari 2008, 2009; Chaudhari and Murthy 2010) shows the separation capability of NF-300 membrane at different feed concentrations. All the experiments are performed at a pH of 5.0 ± 0.1,

feed rate 15 L/min, and applied pressure 4–20 atm. It can be seen from Table 1 that the reflection coefficient decreases with increase in feed solute concentration. It is observed that the reflection coefficient for each salt increases with co-ion valency. Recently, modeling of cadmium removal by nanofiltration using genetic programming was reported (Okhovat and Mousavi 2012). A mechanism related to cadmium salt transport through a nanofiltration membrane was proposed by Garba et al. (2000), and it was found that in most cases convection plays the most important role.

Recovery of cadmium from aqueous effluents by membrane operations. Cadmium is a metal

found in the earth's crust at concentrations ranging from 0.1 to 5 ppm, primarily as sulfide minerals in association with zinc ores, zinc-bearing lead ores, and/or complex copper-lead-zinc ores. The salts of cadmium chloride and cadmium sulfate are soluble in water. Most of the cadmium is extracted through mining. Cadmium is mainly used in batteries (83 %), pigments (8 %), coatings and platings (7 %), stabilizers for plastics (1.2 %), nonferrous alloys, photovoltaic devices, and other uses (0.8 %). Hence, naturally cadmium is mainly recovered from used batteries (Toxicological profile for cadmium 2012). Cadmium is recovered from spent NiCd batteries, copper-cadmium alloy scrap, some complex nonferrous alloy scrap, and cadmium-containing dust from electric arc furnaces (EAF). In 2006, the US steel industry generated about 0.7 million tons of EAF dust, typically containing 0.003–0.07 % cadmium (Mineral Commodity Summaries 2007). Recently, membrane separations are being used to recover/extract the cadmium from different waste streams. Cadmium present in the dust form was most efficiently collected by membrane filters (United Nations Environment Programme: Chemicals Branch 2010). Cadmium, along with other metal ions, was recovered from acidic leach solutions by emulsion liquid membrane (ELM) using trioctylamine (TOA) as extractant (Kumbasar 2009). The results showed (Kumbasar 2009) that up to 98 % cadmium recovery was possible after 10 min contact time by using ELM (Table 1). Jha et al. (2012) and Safarzadeh et al. (2007) show the possibility of extraction and separation of cadmium from different solutions containing other metallic ions. The cadmium extraction efficiencies of three phosphoric acid derivatives such as bis-(2-ethylhexyl) phosphoric acid (D2EHPA), 2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester (PC-88A), and bis-(2,4,4-trimethyl pentyl) phosphinic acid (Cyanex 272) have been reported using supported liquid membrane (SLM) (Fig. 1) (Parhi et al. 2009). Also, several researchers reported the recovery of cadmium by SLM with different extractants (He et al. 2007). Polymer-enhanced ultrafiltration (UF) and nanofiltration

Capillary

Andras Koris
Corvinus University of Budapest, Budapest,
Hungary

The word **capillary** originated from the Latin adjective *capillaris*, which means “pertaining to the hair.” Possibly, the scientific phenomenon was first observed between contiguous hairs, for example, within a paintbrush.

In medicine and biology, capillary is the smallest of a body’s blood vessel and is part of the microcirculation. The word capillary, in the nonmedical sense, means narrow tube.

In membrane science the noun capillary is both used to name the inner spaces of a porous media and to specify a typical membrane (see ► [Capillary Membrane](#)). The classification of porous membrane filter types is mainly based on the nominal diameter of the capillaries in the membrane. Artificial capillaries in porous media are produced by interfacial polymerization, or the natural porosity in solid materials is adjusted to the desirable nominal diameter. The shape and size of the pores in the membrane are very diverse.

The pore theory of membrane transport through the capillaries considers that both convection and diffusion contribute to solute transport across the porous membrane, the two processes being impeded by steric hindrance at the entrance of the pores and by frictional forces within the pores; the same steric hindrance and frictional resistance terms were used in the convection and diffusion terms of the solute transport equation (Pappenheimer et al. 1951).

Capillary Flow

Andras Koris
Corvinus University of Budapest, Budapest,
Hungary

Capillary flow means the movement of the fluid in the internal gaps and on the surface of the solid material, where the driving force is the molecular interaction between the solid and fluid material (see ► [Capillary Force](#)). If the fluid is incompressible and Newtonian, the flow is laminar through a pipe of constant circular cross section that is substantially longer than its diameter, and since there is no acceleration of fluid in the pipe, the total flow rate (Q) could be estimated according to Poiseuille’s law (Briant et al. 1989):

$$Q = \frac{d^4 \pi \cdot \Delta P}{128 \cdot \mu \cdot L}$$

where d represents capillary diameter, ΔP is the total pressure drop along the channel, μ is the fluid viscosity, and L represents the capillary length.

For velocity calculation, let us consider a laminar horizontal flow through a straight circular channel of length L and a radius r . The mean flow velocity u through the channel is given by (Landau and Lifshitz 1987):

$$u = -\frac{r^2}{8\mu} \frac{\Delta P}{L}$$

where ΔP is the total pressure drop along the channel and μ is the fluid viscosity.

In the general case of two immiscible fluids:

$$u = -\frac{r^2}{8\mu_{eff}} \frac{\Delta P - P_c}{L}$$

where

$$\mu_{eff} = \frac{x}{L} \mu_w + \frac{L-x}{L} \mu_a$$

is the effective viscosity; μ_w and μ_a are viscosities for phase w and phase a fluids, respectively; x is the location of the interface measured from the inlet; P_c is the capillary pressure across the interface; and a_0 is a constant associated with the channel cross-sectional shape.

Assuming that the fluid system is in static equilibrium, the capillary pressure at an interface in a circular channel is (Young-Laplace eq.):

$$P_c = \frac{4\gamma \cdot \cos \theta}{d_c}$$

where γ represents the interfacial tension, θ is the contact angle, and d_m represents the capillary diameter.

Since the determination of the number of active capillaries during membrane filtration is very difficult, statistical approach from Darcy can be applied basically. Darcy's law is a simple proportional relationship between the instantaneous discharge rate through a porous medium, the viscosity of the fluid, and the pressure drop over a given distance:

$$Q = \frac{-k \cdot A \cdot \Delta P}{\mu \cdot L}$$

where Q is overall flow rate, k represents permeability of the medium, A is the cross-sectional area to flow, ΔP is the pressure drop, μ represents viscosity, and L is the length over which the pressure drop is taking place.

Due to the concentration polarization phenomenon, gel layer forming, membrane fouling, and pore blocking, the global model was further developed for different membrane techniques, see, e.g., resistances-in-series model or solution-diffusion model.

The diffusion of gasses, liquids, and solids in solids is quite important in mass transfer operations. The diffusion is greatly affected by the size and shape of pores and capillaries. For example, in porous solids, the effective diffusion of salts (A) in water (B) is described as:

$$D_{\{-A, \text{eff}\}} = D_{AB} \frac{\epsilon}{k_2}$$

where D_{AB} represents the diffusivity of salt in water, ϵ is the porosity, and k is a correction factor for the distance (when it is nonlinear; general value = 1.2–2.5).

The diffusion of a liquid in capillaries has three types: Knudsen diffusion, molecular (Fick's) diffusion, and transition region diffusion (Geankoplis 1972).

The power-law is an improvement to the Poiseuille's equation by generalizing the flow to include non-Newtonian effect. The beauty of this model is its simplicity. However there are other aspects of the flow properties of fluids which this model fails to examine, one of them being the presence of yield stress (Mazumdar 1992)

Capillary Force

Andras Koris

Corvinus University of Budapest, Budapest, Hungary

Capillary force is the force which generates movement of a liquid along the surface of a solid caused by the attraction of molecules of the liquid to the molecules of the solid. For example, molecules of water are naturally attracted to each other and form temporary hydrogen bonds with each other; their attraction for each other on the surface of a liquid, for example, gives rise to surface tension. But they are also attracted in a similar way to other molecules, called hydrophilic molecules, such as those in the sides of a narrow glass tube inserted

Capillary Force, Fig. 1 Contact of three fluids

into water. These attractive forces can draw water up against the force of gravity to a certain degree.

Where three different fluid interfaces are contacting each other along one line, equilibrium exists only when the vector polygon of the stresses is closed. This requirement determines the angle between the edges of disjunctive surfaces (Pattantyús 1961) (Fig. 1).

Sometimes $|C1-3| > |C1-2| + |C2-3|$ occurs. Because vector $C1-3$ is always larger, equilibrium is not possible; therefore, fluid no. 2 is permanently moving on the no. 1 and 3 fluid interface. For example, mineral oil unfolds the water surface even to molecule thick layer when the available area is sufficient.

One angle of the vector triangle is given in cases where instead one of the liquids a solid material presents. In Fig. 2 this angle is 180° . The requirement of equilibrium: $C1-3 = C2-3 + C1-2 \cdot \cos\alpha$.

In case of solid particle or material, $|C1-3| > |C1-2| + |C2-3|$ can also exist sometimes, and no. 2 liquid could totally cover the solid surface (1). This movement is usually limited by impurities on the solid surface. For mercury–air–glass system, $|C1-3| < |C2-3|$ and $\alpha > 90^\circ$.

The Young–Laplace equation is a nonlinear partial differential equation that describes the capillary pressure difference or capillary force sustained across the interface between two static fluids, due to the phenomenon of surface tension or wall tension, although usage on the latter is only applicable if assuming that the wall is very thin. The Young–Laplace equation relates the

Capillary Force, Fig. 2 Contact when one solid phase is present next to two fluids

pressure difference to the shape of the surface or wall, and it is fundamentally important in the study of static capillary surfaces. It is a statement of normal stress balance for static fluids meeting at an interface, where the interface is treated as a surface (*scpacp*).

Application Technology, Evonik Fibres GmbH,
Schoerfling, Austria

Synonyms

Capillary membrane; Capillary module

A number of different membrane modules based on capillaries are possible, and all are based on the same membrane geometry with different dimensions as shown in Fig. 1.

The capillary membrane module consists of a large number of capillaries assembled together in a pressure vessel similar as a hollow fiber module (Mulder 1997). The free ends of the capillaries are potted with agents such as epoxy resins, polyurethanes, or silicone rubber. The capillaries are self-supporting. Two types of module arrangements can be distinguished (Mulder 1997):

- Where the feed passes through the bore of the capillary
- Where the feed enters the module on the shell side

The choice between the two concepts is mainly based on the application where parameters such as pressure, pressure drop, type of membrane available, etc. are important. Depending on the

concept applied, asymmetric capillaries are used with their skin on the inside or on the outside (Mulder 1997).

Capillary Membranes

Andras Koris

Corvinus University of Budapest, Budapest,
Hungary

Artificial capillary membranes are one type of the tubular-shaped membrane filters. With capillary membranes, the membrane serves as a selective barrier, which is sufficiently strong to resist filtration pressure. Because of this, the flow through capillary membranes can be both inside out and outside in.

The diameter of capillary membranes is much smaller than that of tubular membranes, namely, 0.5–5 mm. Because of the smaller diameter, the chances of plugging are much higher with a

capillary membrane. A benefit is that the packing density is much greater. The first capillary membrane was fabricated from polymers, but nowadays the technology development enables the production of inorganic capillary modules (Fig. 1).

Description of a Capillary Membrane Module

A complete description of a membrane module requires the simultaneous solution of local transport equations that describe the flow and transport conditions. In a capillary membrane module with a permeable membrane wall, three regions of flow should be considered: flow in the lumen, flow within the membrane matrix, and flow in the extracapillary space. The pressure distribution in the membrane is determined by application of the overall balance of linear momentum. The utilization of this conservation principle is complicated by the fact that an external force must be applied to keep the polymer membrane stationary. In order to describe the behavior of a membrane module, three submodels are required: two that describe the transport on either side of the membrane and a third model that characterizes the separation properties of the membrane and any porous support material (Nagy 2012).

Membrane Development

Besides polymeric and ceramic capillary membranes, other types are also developing due to its

benefits. For example, supported zeolite membranes have been synthesized under microwave heating in order to reduce synthesis time in the work of Sebastian et al. (2010) to prevent support dissolution and to reproducibly obtain a thin defect-free zeolite layer. The MFI-type zeolite membranes were synthesized on ceramic capillaries, with a high membrane surface area-to-volume ratio ($>1,000 \text{ m}^2 \text{ m}^{-3}$), which is by far higher than that of classical tubular supports ($<500 \text{ m}^2 \text{ m}^{-3}$).

In a study of Zhu et al. (2010), alumina microfiltration membranes were prepared on the inner surface of alumina capillary support (outer diameter, 4 mm; inner diameter, 2.5 mm) by a dip-coating method. Scanning electron microscopy (SEM) observation, gas bubble pressure (GBP) method, and membrane permeation test were carried out to evaluate membrane performance. Two major effects in preparation of crack-free membrane, capillary filtration, and film coating upon the thin support were studied.

Bonyadi and Mackley (2012) reported the experimental results for the processing of micro-capillary film (MCF) membranes. MCFs are films with embedded multiple hollow capillaries and can be considered as a hybrid geometry between flat sheet and hollow fibers. Compared to the conventional membrane geometries, MCFs potentially provide a higher surface area per unit volume, better mechanical strength, ease of handling, and more efficient module fabrication. MCF membranes were fabricated out of ethylene vinyl alcohol (EVOH) copolymer through a solution extrusion followed by a nonsolvent induced phase separation (NIPS) process.

Solvent resistant nanofiltration (SRNF) is a membrane separation process allowing for an efficient separation of small molecules of 200–1,000 g mol⁻¹ from organic solvents. The application of SRNF in industry applications is currently hindered by a limited choice of SRNF membranes and configurations. In the work of Dutczak et al. (2011), SRNF composite capillary membranes made of an α -alumina support and a selective poly(dimethylsiloxane) (PDMS) top layer were prepared and studied. We combine the advantages of a ceramic support such as high

mechanical, thermal, and chemical stability with very good separation properties of the PDMS coating.

Possible Applications

The number of practical applications of capillary membranes is also expanding. A new combined method is reported to localize the sites of enzyme immobilization and to determine its catalytic activity on a polymeric capillary membrane reactor activity (Mazzuca et al. (2006)). β -Glucosidase from olive fruit was selected as enzyme model because of its suitable relevance in the industrial processing of foods, in biotechnology, and in pharmaceuticals and for its activity against the synthetic substrate 5-bromo-4-chloro-3-indolyl- β -D-glucopyranoside which develops an insoluble dyed product. The enzyme was physically immobilized within 30 kDa cutoff capillary polysulfone membranes, and results obtained by means of a polyclonal antibody against β -glucosidase and the synthetic substrate clearly showed a coherent localization of the immobilization enzyme sites and its activity.

Commercial flat sheet membranes were compared to capillary one's (Van der Bruggen et al. 2003). For the capillary membrane, the water flux could, however, easily be increased and maintained at a stable level by a combination of forward flushing and airflushing, which is not possible with the flat sheet membranes. Furthermore, the water permeability for the capillary membrane was 3–15 times higher than for the commercial flat sheet membranes, which leads to lower operating pressure and a correspondingly lower energy consumption. For the capillary membrane, rejections of organic and inorganic compounds were satisfactory to reach for COD and conductivity standards in one step starting from the surface water. Rejections for most flat sheet membranes were comparable to the rejections obtained with the capillary membrane, but the rejection of ions was usually higher, except for the N30F and NF PES 10 membranes. Low ion rejections are advantageous for drinking water production because demineralization is avoided.

Suitability of capillary modules to the decolorization of both synthetic and actual dye solutions by ultrafiltration was investigated as well. The process involved capillary membranes made of polysulfone and modified polysulfone. Membrane modules (UFTA PS10, UFTA PS30, and UFTA PSA50) of various molecular cutoffs were applied (Majewska-Nowak et al. 1996).

Investigations concerning the application of ceramic and capillary microfiltration and ultrafiltration membranes for the purpose of treatment of natural water were carried out by Bodzek and Konieczny 1998. The effectiveness of ultra- and microfiltration was assessed by volumetric measurements of the permeate flux as well as by microbiological and physicochemical analyses.

Analysis of oxygen permeation fluxes through Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_{3- δ} (BSCF) capillary membranes, fabricated via a phase inversion spinning technique using polysulfone as binder, showed a significant limiting role of the surface oxygen exchange kinetics. Within the studied temperature and oxygen partial pressure ranges, the activation of core and shell sides of the BSCF capillary with praseodymium oxide (PrOx) resulted in an increase in permeation rate of about 300 % (Kovalevsky et al. 2011).

Capillary membrane diffusion scrubber (CMDS) was scaled down to match with capillary electrophoresis (CE), a quick separation technique that requires nothing more than some nanoliters of sample and, when combined with capacitively coupled contactless conductometric detection (C4D), is particularly favorable for ionic species that do not absorb in the UV–vis region, like the target analytes formaldehyde, formic acid, acetic acid, and ammonium (Coelho et al. 2010).

Ceramic tube and ceramic capillary membranes and their effect on permeate flux, oil retention, and specific energy consumption were compared in the work of Gáspár et al. (2011). The results, obtained with a stable oil-in-water microemulsion as feed, demonstrated that the use of novel ceramic capillary membranes at optimal operating cross-flow velocity and transmembrane pressure is reasonable.

Capillary Module

► Capillary Membrane Module

Capillary Tubes

Andras Koris

Corvinus University of Budapest, Budapest, Hungary

Def. (Engineering) A tube sufficiently fine so that capillary attraction of a liquid into the tube is significant. (General Physics) A glass tube with a fine bore and thick walls, used in thermometers, etc. (Medical) Glass capillary tubes are used for the collection of blood in a variety of healthcare settings, including hospitals, ambulatory care facilities, physicians' offices, blood donation facilities, and blood testing centers.

Basic Description

A capillary tube works by its being tension pulling between the circumference and the inner wall of the tube. The restriction and metering of the liquid will maintain pressure differential. See more at

► Capillary Force.

Capillary tubes can be made of different materials like plastic, glass, stainless steel, and ceramics.

Wall thickness of microhematocrit capillary tubes is 0.01 mm.

Applications

It can be a device used to measure kinematic viscosity. Kinematic viscosity is the time it takes for a fixed amount of fluid to move through a measured length of the capillary tube with gravity alone.

In Membrane Science once capillary tubes present in the filter media, they are called pores. Symmetric pore structure is usually formed by pressing and sintering, extruding and stretching, irradiation and etching, template leaching, or phase inversion. On the other hand, capillaries can be found in capillary membranes as well.

Capillary tubes are used in analytical applications, such as chromatography, gas and liquid lines, and measurement components in remote thermometer systems (with or without compensation).

An indispensable capillary tube is used for calculating blood clotting time or determining melting points.

Also a capillary tube is used in refrigeration and air-conditioning systems. It is a copper tube that has a small internal diameter. A capillary tube functions by dropping pressure due to its small internal diameter. The refrigerant leaves the condenser and enters the capillary tube and when it reaches the capillary tube falls in pressure and keeps the pressure constant. It limits the maximum amount of the refrigerant that can be charged in the refrigeration system.

Carbon Capture and Storage (CCS)

Colin A. Scholes

Department of Chemical and Biomolecular Engineering, University of Melbourne, Parkville, VIC, Australia

Carbon capture and storage (CCS) is a proposed strategy to separate carbon dioxide from industrial gases and store that carbon on a geological time-scale. This is a response to the perceived threat industrial carbon dioxide emissions have in producing anthropogenic climate change (IPCC 2007). CCS is divided into three distinct stages, the capture of the carbon dioxide from the emission source, the compression and transportation of CO₂ to the storage site, and the final storage of CO₂ for long periods of time (IPCC 2005).

The capturing of CO₂ is predominately associated with large stationary point sources and in particular coal-fired power stations. The strategies to capture carbon emissions from these sources can be classified into three distinct approaches: post-combustion capture, oxy-fuel combustion, and precombustion capture (Table 1).

Post-combustion capture is the separation of CO₂ from flue gases after the combustion process.

This is primarily a separation of CO₂ from N₂, as well as water and other minor components, such as CO, SO_x, and NO_x. The separation process occurs at lower pressures, low CO₂ partial pressures, and often around ambient temperature. Oxy-fuel combustion is pure oxygen firing of the combustion process. This excludes N₂ from the combustion zone and produces a flue gas consisting of CO₂ and H₂O. Carbon capture is achieved through water removal. However, the very high flame temperature often dictates flue gas recycling, and critically this strategy requires the separation of high purity O₂ from air, which is commonly achieved through cryogenic methods. Precombustion capture is the gasification of the carbon-based fuel into synthetic gas, also called syngas, consisting of CO and H₂. This syngas is an important industrial feed gas that is used in a wide range of processes, such as Fischer-Tropsch synthesis. For power generation, H₂ production is often maximized through the water gas shift reaction, resulting in high-pressure gas mixtures of CO₂, CO, and H₂. Separation of CO₂ is achieved before H₂ undergoes combustion. This separation strategy takes advantage of the high pressure and CO₂ partial pressure before combustion.

Carbon capture has also been applied to other industrial applications, such as natural gas sweetening, for the removal of acidic gases to meet pipeline specifications, as well as in natural gas reforming for ammonia production.

A range of separation technologies have been applied to carbon capture, including solvent separation, membrane gas separation, adsorption technology, cryogenic separation, and mineral carbonation. The current commercial technology of choice is physical and chemical solvent technology, with membrane gas separation having been commercial proven in natural gas sweetening.

Transportation of captured CO₂ to the storage site is undertaken through shipping (low temperature and low pressure) or pipelines (high pressure and ambient temperature). The method of transportation is dependent on distance and geography between the source and storage sites.

Storage of carbon for extended periods of time can be achieved through geosequestration, deep ocean storage, or mineralization. Geosequestration

Carbon Capture and Storage (CCS), Table 1 Carbon capture strategy conditions and gas compositions

	Post-combustion	Oxy-fuel combustion	Precombustion
Pressure (bar)	1	1	30
Composition (mol. frac.)			
CO ₂	0.11	0.87	0.40
N ₂	0.62	–	–
H ₂	–	–	0.55
O ₂	0.04	0.05	–
H ₂ O	0.23	0.08	0.02
CO	–	–	0.03

is the injection of supercritical CO₂ into geological formations, generally sedimentary basin, over a kilometer underground. Importantly, the geological formation must contain a suitable reservoir rock, with high permeability and porosity for CO₂, as well as a seal rock above the reservoir that forms the necessary geological trap. Possible geological sites for CO₂ geosequestration include disused oil and gas fields, saline aquifers, as well as deep coal seams. Currently, CO₂ is geosequestered commercially as part of enhanced oil recovery procedures.

Carbon Clothes in Fuel Cells

Rajnish Kaur Calay
Institute for Building, Energy and Material
Technology, University of Tromsø, Navrik,
Norway
Energy Technology Research Group, Narvik
University College, Lodve Langes gt 2, Navrik,
Norway

Carbon cloth is used as gas diffusion layers (GDL) in fuel cells. The GDL is an essential

component in the fuel cell which performs several functions such as to distribute reactant gases, water management, and electrical conduction. Carbon cloth is one of the two preferred materials (other one is carbon paper) for GDLs in polymer electrolyte membrane fuel cells (PEMFC) and direct methanol fuel cells (DMFC).

Carbon cloth is commercially available in thickness of about 300–450 µm. Carbon cloth is made by weaving carbon fibers and therefore is more flexible and resilient than carbon paper-based GDL layers. Because carbon cloth is electrically conductive, it also provides pathway for current collection. Therefore carbon cloth GDL acts as electrical connection between the bipolar plate and the catalyst layer (reaction layer) where the electrons are liberated/consumed in the electrochemical reactions involved inside the fuel cell. Carbon cloth offers good porosity to allow easy passage of reactants (i.e., gas) to diffuse to the catalyst layer for more uniform reaction. The good porosity of carbon cloth also helps in the removal of products of the fuel cell reaction, i.e., water and oxygen depleted air, while the heat is transferred away from the reaction site to other components inside the cell. It is important to prevent the flooding of the GDL; therefore carbon cloth is made wet proof typically with a hydrophobic coating (e.g., PTFE or Teflon). Carbon cloths are often highly compressible, reaching up to 40–50 % compression when in a stack. This compression can significantly change their electrical and gas permeation properties and therefore careful consideration is required when using carbon cloth as a GDL.

Carbon Dioxide (CO₂) Separation by Membranes

Colin A. Scholes

Department of Chemical and Biomolecular Engineering, University of Melbourne, Parkville, VIC, Australia

Carbon dioxide (CO₂) separation by membranes has been proposed for a range of carbon capture and storage strategies. To date, CO₂-selective membranes have only been commercialized for natural gas sweetening, though a range of membrane pilot plants are currently assessing the feasibility for CO₂ separation from syngas and flue gas. In all of these applications, the CO₂-selective membrane is based on nonporous polymeric membranes. These operate on the solution-diffusion mechanism and take advantage of the strong CO₂ solubility within the polymeric matrix relative to other gases, such as N₂ and H₂. In particular, glassy polymeric membranes are applied to CO₂ separation from flue gas and natural gas, because of the high permeabilities and selectivities possible for these types of polymers. While, for CO₂ separation from syngas, rubbery polymeric membranes are the focus, because these can provide the CO₂/H₂ selectivity needed for CO₂ separation. Molecular sieving and surface diffusion membranes based on porous inorganic and nanoporous carbon materials have been developed that are CO₂ selective. However, there is currently no industrial plant or pilot trials of these membranes.

The first CO₂-selective membrane to be commercialized was cellulose acetate, for the natural gas sweetening industry. Generally, these membranes are a combination of cellulose acetate, cellulose diacetate, and cellulose triacetate and have CO₂ permeabilities on the order of three to six barrer and CO₂/CH₄ selectivities of 25–40. Currently, cellulose acetate membranes make up to 80 % market share of membranes in natural gas processing, and modules of both spiral wound and hollow fiber designs can be purchased (Scholes et al. 2012). Cellulose acetate-based membranes are currently commercialized under the names Cynara[®] (part of Cameron) and UOP Separex[®] (part of Honeywell).

The second generation of CO₂-selective membranes are based on polyimides. These types of membranes generally display higher permeabilities and selectivities for CO₂ than cellulose acetate-based membranes. These have a CO₂ permeance range of 10–200 GPU and a CO₂/CH₄ selectivity range of 5–30. Polyimide modules are predominately hollow fiber design and have been commercialized by UBE Industries and Air Liquide. Other CO₂-selective membranes that have been commercialized are based on perfluoropolymers and are currently only applied in niche processes (Merkel et al. 2006).

A wide range of other nonporous polymeric membrane materials have been reported in the literature for CO₂ separation, such as polybenzoxazoles, polysulfones, polycarbonates, and polypyrroles (Powell and Qiao 2006). Facilitated transport mechanism selectivity for CO₂ has also been developed, especially for syngas applications. Many of these materials display high CO₂ permeances and CO₂ selectivities relative to other gases present. However, none of these membrane materials have been successfully commercialized to date.

Carbon Membrane

May-Britt Hägg

Department of Chemical Engineering, Norwegian University of Science and Technology, Trondheim, Norway

Carbon membranes are usually characterized as carbon molecular sieves (CMS membranes) as

they basically separate based on molecular size. This means that the pores can be tailored for a specific gas mixture, permeating the smallest molecule and retaining the larger ones.

There are two main ways of preparing the CMS membranes: pyrolysis of polymeric hollow fibers or performing pyrolysis of a polymer sprayed onto a ceramic support tube. In both cases a pyrolysis protocol needs to be developed for the specific polymer and pores to be obtained. Important variables to be controlled during the pyrolysis is heating rate, soak time, final carbonization temperature, and which gas to use as purge (typically an inert gas or CO_2) vacuum may also be used. Each of these variables will influence the final pore size and separation properties of the membrane. The final carbonization temperature is usually in the range of 500–900 °C. Carbon membranes are fairly easy to produce on lab scale as much is known on how carbonization conditions affect separation properties (Geiszler and Koros 1996; He and Hägg 2012). However, the scaling up to commercial-size modules may be more of a challenge as commented on further down.

The first carbon membranes were prepared from carbonization of cellulose hollow fibers by Koresh and Soffer (1983). Since then various polymers have been used such as polyimides, polyacrylonitrile (PAN), poly(phenylene oxide) (PPO), cellulose derivatives, and others. The separation properties of CMS membranes are very attractive as their sieving properties easily exceed the upper Robeson boundary of permeability versus selectivity trade-off relationship (Robeson 2008) – this makes it also attractive for industrial applications. The making of the membranes may thus involve six steps: material selection, material functionalization, precursor preparation, pretreatment, carbonization, and possibly posttreatment (Fig. 1). Functionalization usually means adding a porogen or a metal salt to the precursor. The porogen will degrade during the carbonization and thereby increase the pore volume. When the additive is a metal salt (doping the precursor), the final CMS membrane will contain the metal which may functionalize the membrane by showing high affinity to one of the permeating gases (Lie and Hägg 2005). Then if using posttreatment, surface modifiers may adjust

Carbon Membrane,

Fig. 1 Comparing the CO_2/CH_4 Robeson upper bound for dense and thermally rearranged (TR) polymer membranes to the carbon membranes and the region for industrial applicability – data for CMS membranes and industrial applicability region added to the original Robeson plot (see Hägg and He 2011)

Carbon Membrane, Fig. 2 Schematic model of different ways of tailoring microporous carbon. The *dashed line* shows the limit of an original slit-shaped pore (Lie and Hägg 2005)

Carbon Membrane,

Fig. 3 *Left:* SEM picture of a CMS fiber; wall thickness is 16 μm . *Right:* A bundle of CMS hollow fibers ready for mounting in a pilot module as illustrated by the company MemfoACT in 2013 on their homepage

the pore size. A big advantage of carbon membranes is that they may be used for high-temperature gas separations. This advantage may, however, be compromised if the surface modifier is a degradable polymer at process operation temperature. The different ways of tailoring microporous carbon membranes are illustrated in Fig. 2 (Lie and Hägg 2005).

Although showing excellent separation performance, the self-supported hollow fiber membranes may be quite brittle, thus the scaling up and module making are challenging. The Norwegian company MemfoACT did successfully demonstrate on pilot scale the use of carbonized self-supported cellulose hollow fibers for upgrading of biogas (CO_2/CH_4 separation) (Fig. 3). The scaling up to full-size commercial module has however not yet been reported (in 2015).

The supported carbon membranes will provide better mechanical strength than self-supported fibers but will naturally have lower packing density. These types of carbon membranes have been

especially studied for high-temperature applications (e.g., H_2/CO_2 separation and as carbon membrane reactors). The special challenge of making these membranes is to obtain a defect-free carbon layer on the top of the support – compatibility between support and carbon layer may also be a problem. Supported CMS membranes have been studied by several. A method by using spin-coat technique was developed already in 1996 by Rao and Sirkar (1996). Stainless steel disks (Acharya and Foley 1999) as well as porous α -alumina tubes (Zhou et al. 2003) have been reported as suitable support for pyrolyzed carbon membranes. Acharaya and Foley studied the separation of O_2/N_2 and obtained a separation factor of 12. A challenge of concern with respect to any CMS membrane is the possibility of aging, whereby separation performance may decline over time; hence, the membranes need to be regenerated. Several ways are proposed, such as using heat, purging with air or propane, or using low-voltage direct current at

intervals (Lie and Hägg 2006). The research on CMS membranes is however continuously moving forward, and is well documented, and example is Fu et al. (2015). The main challenge still seems to be scaling up to commercial-size modules.

Potential of Applications

Due to the possibility of tailoring the pores, the CMS membranes have a very nice potential of separating gas pairs which are difficult to separate using other type of membranes and gases which are much alike in structure and physical properties, typically O_2/N_2 and C_3H_8/C_3H_6 (olefin/paraffins in general) (Yoshino et al. 2003). Other type of gas separations can typically be CO_2/CH_4 (both as biogas and as natural gas) and recovery of hydrogen from gas streams such as H_2/CO_2 (precombustion) and H_2 from refinery gasses.

⁴Center of Excellence in Desalination Technology, King Abdulaziz University, Jeddah, Saudi Arabia

Carbon nanotubes (CNTs) are allotropic forms of carbon that can be conceptually visualized as a cylindrical nanostructure formed by rolling a graphene sheet along a lattice vectors (m,n) in the graphene plane (Fig. 1).

Depending from the number of concentric cylinders, it is possible to have: single-, double-, or multiwalled carbon nanotubes (SWCNTs, DWCNTs, MWCNTs). The indices (m,n) determine the diameter and chirality (i.e., the chiral angle between hexagons and the tube axis) of the CNTs (Dai 2002). The CNTs can be in the zigzag, armchair, or chiral form with metallic or semiconducting properties (Table 1).

CNTs, thanks to their diameter in the nanometer range and their atomically smooth surfaces,

Carbon Nanotube Membranes

(CNT Membranes),

Fig. 1 Schematic honeycomb structure of a graphene sheet (sp^2 hybridized carbon network) (a) and image of single-, double-, and multiwalled carbon nanotubes (SWCNTs, DWCNTs, MWCNTs), (b)

offer unique systems for fast molecular transport (Hummer et al. 2001; Kalra et al. 2003). Molecular dynamics (MD) simulations showed spontaneous and continuous filling of a CNT with a one-dimensionally ordered chain of water molecules.

Membranes made of ordered arrays of carbon nanotubes well aligned along the direction perpendicular to the substrate surface have been already synthesized in which the transport occur through the inner core of the CNTs (Majumder et al. 2011). High permeability enhancement than predictions (>10 for gases and >1000 for liquids) have been obtained with these membranes. However, the small area (typically in the order of few μm^2), the long and complex fabrication process, and the poor mechanical stability of these type of CNT membranes, limit the practical applicability of these interesting nanostructured systems. On the contrary, more easy is the scale up of CNT membranes in which the CNTs are mixed with a polymer in the form of mixed matrix membranes. The main limitations of these membranes are related to the poor dispersion of the CNTs in the polymeric matrix and the moderate increase of the membrane performance.

It is interesting to note that graphitic carbon nanomaterials like CNTs are usually introduced at lower content (≤ 2 wt%) in mixed matrix membranes in comparison with three-dimensional inorganic nanofillers like TiO_2 and ZrO_2 (usually blended at loading ≥ 5 wt%, up to 60 wt%), thank to their high specific surface, elevated aspect ratio, and the intrinsic properties of graphitized structure. In addition, the relatively easy functionalization of the surface of carbon nanomaterials render them ideal candidate to tailor the polymer/nanofiller interface.

CNTs were successfully entrapped in mixed matrix membranes made of various polymeric materials by several techniques including: dispersion in the casting solution and successive phase separation, entrapping in the membrane pores using a polymer binder, in situ crosslinking of a polymer matrix around oriented CNTs (Ismail et al. 2009). The resulting mixed matrix CNT membranes offer, in many cases, relevant advantages in comparison with the polymeric samples. Poly(vinyl alcohol) (PVA)/MWCNTs membranes were realized for pervaporation application, obtaining significant improvement in Young's modulus and thermal stability, as compared to

pure PVA membranes (Peng et al. 2007). The entrapment of MWCNTs in polyethersulfone (PES) membranes reduced fouling problems in water treatment (Celik et al. 2011). Mixed matrix membranes consisting of sulfonated carbon nanotubes (sCNTs) and sulfonated poly (ethersulfone ether ketone ketone) (SPESEKK) were also fabricated via the solution casting method (Zhou et al. 2011). The proton conductivity of the SPESEKK membrane increased while the methanol permeability decreased as the sCNTs content increased. MWCNTs were covalently linked to aromatic polyamide (PA) membranes by a polymer grafting process (Shawky et al. 2011). Measurements of mechanical properties

of this composite showed an increased membrane mechanical strength relative to the PA polymeric membranes.

Mixed matrix polyimide membranes were also prepared using functionalized MWCNTs (aminated or oxidized). The MWCNTs functionalization improved their dispersion in the casting solution in comparison to pristine MWCNTs and, as a consequence, in the formed membranes. The membranes containing functionalized MWCNTs showed better performance in the rejection of dyes (enhanced flux and reduced fouling, with similar or higher rejection), with respect to reference polymeric membranes (without MWCNTs). These results were attributed to the formation of low-resistance pathways for solvent transport at the interface between the MWCNTs and the polymeric chains. Moreover, the MWCNTs reduced the severe membrane fouling caused by the absorption of the positively charged dye Safranin (used as a model of organic pollutant) with respect to the polymeric membrane, by a screening effect of the attractive electrical interactions between the Safranin and the membrane surface characterized by a negative value of zeta potential (Grosso et al. 2014).

The presence of oxygen-containing polar groups on oxidized MWCNTs, resulted also in a good dispersion in polyvinylidene difluoride (PVDF) membranes, allowing the formation of mixed matrix membranes with a lower fouling tendency in comparison with the bare polymeric samples (Fontananova et al. 2014).

MWCNTs were also immobilized in the pores of a hydrophobic membrane improving the water-membrane interactions to promote vapor permeability in membrane distillation process (Gethard et al. 2011). In this case, the CNTs dispersion was forced under vacuum into the pores of a polypropylene (PP) membrane, using PVDF as binder.

Carbon Porous Membranes Modified with Enzymes

Christophe Innocent

Institut Européen des Membranes, ENSCM, CNRS, Université de Montpellier, Montpellier, France

The carbon porous tubes (from Novasep-Orelis-France) have been characterized by average pore diameter of 3 mm and an inner diameter of 0.6 cm (Fig. 1).

The immobilization of enzyme on the carbon tube surface has been carried out by dipping in enzyme solution and then addition of pyrrole monomer just before starting the anodic electropolymerization at +0.9 V vs. Ag/AgCl. The oxidation of pyrrole allowed the entrapment of enzyme in polypyrrole coated on the electrode surface.

A glucose/O₂ biofuel cell is based on tubular cathode (coated with laccase/ABTS on the external surface for dioxygen reduction) and the tubular anode (coated with glucose oxidase enzyme (GOD) and hydroxyquinoline sulfonic acid as mediator) on the internal surface for glucose oxidation.

The two electrodes were soaked in an unstirred 10 mM glucose solution. Glucose diffused through the polypyrrole film to be oxidized by the GOD at the anode. In order to prevent the presence of dioxygen in the vicinity of GOD, dissolved oxygen was supplied to the system by

Carbon Porous Membranes Modified with Enzymes,

Fig. 1 Photography of carbon tube (photo IEM)

Carbon Porous Membranes Modified with Enzymes,
Fig. 2 Scheme of concentric biofuel cell (thesis of G. MERLE, University Montpellier 2, 2008)

circulating through the inner cavity of the biocathode, then before being reduced at the external surface by the BOD.

Cylindrical and porous carbon tubes were used as original conducting support for the compartment of the bioelectrodes, for enzyme immobilization and transport of dissolved oxygen via diffusive flow through the porosity (Fig. 2). The resulting glucose/oxygen biofuel cell is operated at a maximum power density of 42 mWcm^{-2} at 0.3 V and 37°C in phosphate buffer pH 7.4.

Carman–Kozeny Equation

Boguslaw Kruczek
 Department of Chemical & Biological
 Engineering, University of Ottawa, Ottawa, ON,
 Canada

Introduction

The Carman–Kozeny equation (or the Kozeny–Carman equation) is a relation to calculate

the pressure drop for laminar flow through a packed bed of solids. It was originally developed by Kozeny in 1927, using the simplified model of a number of parallel capillary tubes of equal length and diameter to describe the packed bed (McCabe et al. 2005). The Kozeny equation is given by

$$\frac{\Delta p}{L} = \frac{KV_o\mu}{\Phi_s^2 D_p^2} \frac{(1-\varepsilon)^2}{\varepsilon^3} \quad (1)$$

where Δp is the pressure drop, L is the total height of the bed, V_o is the superficial or “empty-tower” velocity, μ is the viscosity of the fluid, ε is the porosity of the bed, Φ_s is the sphericity of the particles in the packed bed, D_p is the diameter of the equivalent spherical particle, and K is an empirical constant, which depends on bed tortuosity. The sphericity of a particle is defined by

$$\Phi_s = \frac{6/D_p}{a_v} \quad (2)$$

where a_v is the specific surface area of the particle. If the bed is made of uniform particles, the a_v of the particle represents the specific surface of the bed. The a_v of the particle is simply the surface-volume ratio, i.e., $a_v = s_p/v_p$, where s_p is the surface area of the particle and v_p is the volume of the particle. It follows that for a sphere with the diameter D_p , $a_v = 6/D_p$ and $\Phi_s = 1.0$.

In 1937 Carman applied Eq. 1 to experimental results of flow through packed beds and found that $K = 180$ (Foust et al. 1980). Other references also suggested the value of $K = 150$ (Seader et al. 2011). The Carman–Kozeny equation indicates that the flow is proportional to the pressure drop and inversely proportional to the fluid viscosity. This statement is also known as Darcy’s law, which is often used to describe flow of liquids through porous media.

Extension of the Carman–Kozeny Equation

The Carman–Kozeny equation is applicable for flow through beds at particle Reynolds number (Re_p) up to about 1.0, and

$$\text{Re}_p = \frac{V_o D_p \rho}{\mu} \quad (3)$$

where ρ is the density of fluid. As the flow rate through a packed bed increases, the pressure drop becomes a stronger function of the superficial velocity. At $\text{Re}_p > 1,000$ the pressure drop in packed beds is described by an empirical relation often referred to as the Burke–Plummer equation (McCabe et al. 2005):

$$\frac{\Delta p}{L} = \frac{1.75 \rho V_o^2}{\Phi_s D_p} \frac{1 - \varepsilon}{\varepsilon^3} \quad (4)$$

An equation covering the entire range of flow rates is obtained by assuming that the pressure drop due to viscous losses (Eq. 1) and the pressure drop due to the kinetic energy losses (Eq. 4) are additive. The result is called the Ergun equation (McCabe et al. 2005):

$$\frac{\Delta p}{L} = \frac{K V_o \mu}{\Phi_s^2 D_p^2} \frac{(1 - \varepsilon)^2}{\varepsilon^3} + \frac{1.75 \rho V_o^2}{\Phi_s D_p} \frac{1 - \varepsilon}{\varepsilon^3} \quad (5)$$

The sphericity often does not appear in Eq. 5, which implies the particles in the bed are nearly spherical ($\Phi_s \approx 1$).

Carman–Kozeny Equation in Membrane Processes

The transport of fluid in ► **ultrafiltration (UF)** and ► **microfiltration (MF)** processes is driven by a pressure difference across the membrane (Δp). The UF and MF membranes are porous with the pore size ranges of 2–100 nm and 0.1–10 μm , respectively (Mulder 1996). Because of very small pore sizes, the flow velocity in an idealized straight cylindrical pore of a UF or MF membrane is governed by the Hagen–Poiseuille law (Seader et al. 2011):

$$V = \frac{D^2}{32 \mu L_M} \quad (6)$$

where D is the pore diameter and L_M is the membrane thickness. The mass velocity of fluid (N in

$\text{kg} \times \text{s}^{-1} \times \text{m}^{-2}$) through the membrane is then obtained by multiplying the flow velocity by fluid density and membrane porosity:

$$N = \frac{\varepsilon \rho D^2}{32 \mu L_M} \Delta p \quad (7)$$

In real porous membranes, the pores may not be cylindrical and straight, and Eq. 7 is modified by using the procedure developed by Carman and Kozeny, in which the pore diameter is replaced by the hydraulic diameter (D_H):

$$D_H = \frac{4 A_p}{P} \quad (8)$$

where A_p is the cross-sectional area of the pore and P is the wetted perimeter of the pore. Expressing A_p and P in terms of the specific surface area and the porosity of the membrane leads to an alternative expression for D_H (Seader et al. 2011):

$$D_H = \frac{4 \varepsilon}{a_v (1 - \varepsilon)} \quad (9)$$

The actual pore length is longer than the membrane thickness and can be represented by τL_M , where τ is a tortuosity factor > 1 . Substituting Eq. 9 and the tortuosity factor into Eq. 7 gives

$$N = \frac{\varepsilon^3 \rho}{2(1 - \varepsilon)^2 a_v^2 \mu \tau L_M} \Delta p \quad (10)$$

Equation 10 is an alternative representation of the Carman–Kozeny equation. Recognizing that $\Phi_s D_p = 6/a_v$, the actual fluid velocity in the bed $V = V_o/\varepsilon$, replacing L by L_M , and multiplying by the fluid density ρ , Eq. 1 can be rearranged to

$$N = \frac{\varepsilon^3 \rho}{(K/36)(1 - \varepsilon)^2 a_v^2 \mu L_M} \Delta p \quad (11)$$

If $K = 150$, the comparison of Eq. 10 with Eq. 11 leads to $\tau = 2.08$; on the other hand, with $K = 180$ $\tau = 2.5$. In other words, the numerical

value of the empirical constant in the Carman–Kozeny equation depends on the tortuosity of the packed bed, which in general ranges from 2.0 to 2.5. In the case of the porous membranes, the tortuosity can be greater than that of the packed bed.

The porosity and the specific surface area of porous membrane can be determined experimentally. If the membrane tortuosity along the membrane thickness is known, Eq. 10 allows to predict the mass velocity of fluid through the membrane under a given pressure gradient across the membrane. Alternatively, for a given mass fluid velocity, Eq. 10 can be used to predict the required pressure gradient across the membrane.

The mass velocity of fluid through the membrane can also be expressed in terms of bulk-flow permeability (P_M), which is a measure of the membrane productivity (Seader et al. 2011):

$$N = \frac{P_M}{L_M} \Delta p \quad (12)$$

It follows from the comparison of Eq. 10 with Eq. 12 that the bulk-flow permeability in porous UF and MF membranes is given by

$$P_M = \frac{\varepsilon^3 \rho}{2(1 - \varepsilon)^2 a_v^2 \mu \tau} \quad (13)$$

The rearranged form of the original Carman–Kozeny equation given by Eq. 11 can be used to predict the bulk-flow permeability of microfiltration membranes prepared by sintering. This method of membrane formation involves compressing a powder consisting of particles of a given size and sintering at elevated temperatures (Mulder 1996). Consequently, the final membrane has a structure similar to that of the packed bed.

The Carman–Kozeny equation is also applicable for the analysis of membrane processes in which the transport of fluid through the membrane is associated with cake formation on the membrane surface (Mulder 1996). In this case, the fluid which permeates through the membrane must overcome two resistances in series, the resistance to flow through the cake (R_C) and the

resistance to the flow through the membrane (R_M). Consequently, the expression for the mass velocity of fluid can be written as follows:

$$N = \frac{\Delta p}{\mu(R_C + R_M)} \quad (14)$$

and

$$R_C = \left(\frac{K}{36} \right) \frac{(1 - \varepsilon)^2 a_v^2 \mu L_C}{\varepsilon^3 \rho} \quad (15)$$

$$R_M = \frac{2(1 - \varepsilon)^2 a_v^2 \mu \tau L_M}{\varepsilon^3 \rho} \quad (16)$$

If there is no adsorption of solute particles inside the membrane pores, R_M is constant, but since the cake thickness (L_C) increases with the amount of feed processed through the membrane, R_C increases accordingly. Equations 14, 15, and 16 are analogous to those used to describe the conventional cake filtration.

Carrier-Mediated Transport

Gerardo León
Departamento de Ingeniería Química y
Ambiental, Universidad Politécnica de Cartagena,
Cartagena, Spain

Transport mechanism used to improve flux, permeability, and selectivity in membrane separations. It is also known as type 2 facilitated

transport or carrier-facilitated transport (Ho and Li 1992). A carrier reagent is incorporated in the membrane phase to transfer the diffusing specie from the feed phase to the product phase across the membrane phase. Although fixed carriers (bonded within the membrane solid matrix either by electrostatic forces or by covalent linkages) have been described, liquid membranes employ mobile carriers, i.e., compounds (soluble in the membrane phase but insoluble in the feed and the product phases) which are added to the membrane phase to form with the specie to be separated into a reversible compound or complex, soluble in the membrane. This compound is formed in the interface feed phase/membrane phase, it is transported through the membrane phase due to its concentration gradient, and it is broken in the membrane phase/product phase interface. Then, the specie to be separated is liberated in the product phase, and the carrier diffuses in the contrary way through the membrane phase, as a consequence of its concentration gradient, to the opposite interface, to initiate a new separation cycle. So, the transport of the target species can be broken down to the following steps: (1) diffusion of the target specie from

the bulk feed phase across the aqueous boundary layer to the feed phase/membrane phase interface; (2) formation of carrier-target specie compound; (3) diffusion of the carrier-target specie compound across the membrane; (4) breakage of the carrier-target specie compound at the membrane phase/product phase interface, releasing both the target specie and the carrier; (5) diffusion of the released target specie from the membrane phase-product phase interface to the bulk strip phase; (6) return of the released carrier across the membrane to the feed phase/membrane phase interface (Marr and Knopp 1982). In this way, each carrier molecule is able to transport solute molecules as many times as necessary, so that only a small amount of the carrier is required in the membrane phase even for achieving a high degree of separation. As the process ends when the concentration of the specie to be separated equalizes on both sides of the membrane, carrier-mediated transport can be improved by incorporating a chemical reaction on the receiving side in two ways. The first is by reducing the concentration of the specie to be separated to practically zero on the product side through an auxiliary reaction in the product phase,

Carrier-Mediated Transport, Fig. 1 (a) Carrier-mediated transport of an acid with tri-n-octylamine, (b) carrier-mediated co-transport of a metallic ion and its accompanying anion with a calixarene derivative

(CLXD), (c) carrier-mediated counter-transport of a metallic ion by an organophosphorus carrier (HR)₂, and (d) carrier-mediated co-transport of a metallic ion and accompanying anion and cation with a crown ether (DC18C6)

to form a compound insoluble in the membrane and release the carrier to begin a new separation cycle. The second is by maintaining the driving force for the transport of the target specie through maintaining a concentration gradient of a second specie transported in the opposite direction. Carrier-mediated transport combines the process of extraction and stripping in a single unit operation, and it offers the possibility of transporting a component against its own concentration gradient (Ho and Li 1992; Kislik 2010). In carrier-mediated transport, two different species can be transported at the same time, giving a coupled transport, in which the membrane contains a carrier which can only lead to transport when two different species present themselves at the same time. If the transport of the two species occurs in the same direction (from the feed to the product phase), we can speak of co-transport. On the other hand, if it occurs in opposite directions (one is transported from the feed to the product phase and the other from the product to the feed phase), we can speak of counter-transport. Different examples of carrier-mediated transport are shown in Fig. 1.

Cascade Diafiltration

Greg Foley
School of Biotechnology, Dublin City University,
Dublin, Ireland

Cascade systems may be used when the product is in the permeate of a microfiltration or ultrafiltration system.

Consider a two-stage cascade. Constant volume diafiltration is performed in the first stage to maximize the recovery of the product which passes through the membrane. The product-containing permeate enters the second stage where it undergoes batch ultrafiltration using a membrane which retains the product.

Cascades can be operated in open-loop or closed-loop configurations (Charcosset 2012). In the open-loop configuration, the permeate from the second stage goes to drain. In the closed-loop configuration, the permeate from the second stage is used as the diluant for the first stage, thus reducing substantially the volume of fresh diluant required.

Cassie–Baxter Model

Wolfgang M. Sigmund and Shu-Hau Hsu
Department of Materials Science and
Engineering, University of Florida, Gainesville,
FL, USA
Department of Energy Engineering, Hanyang
University, Seoul, Republic of Korea

The Wenzel regime is usually recognized as homogeneous wetting, since the liquid completely penetrates into the grooves. While under some circumstances, especially the increase of the surface roughness, vapor pockets may be trapped underneath the liquid yielding a composite interface. This heterogeneous wetting is usually described by the Cassie–Baxter (CB) model, from which the apparent contact angle (θ_{CB}) is given by equation: (Cassie and Baxter 1944)

$$\cos \theta_{CB} = f_s \cos \theta_c + f_v \cos \theta_v \quad (1)$$

where θ_c is the intrinsic contact angle on the original smooth surface and f_s and f_v are the area

Cassie–Baxter Model, Fig. 1 Vapor pockets are trapped between the grooves and the liquid droplet. This state is essential for superhydrophobicity and is described by

Cassie-Baxter model (Hsu et al. 2011, reproduced with permission from Elsevier Ltd.)

fractions of the solid and vapor on the surface, respectively. Since $f_s + f_v = 1$ and $\theta_v = 180^\circ$ (implying that a suspended liquid droplet in air is a perfect sphere), Eq. 1 can be rewritten as follows:

$$\cos \theta_{CB} = f_s (\cos \theta_c + 1) - 1 \quad (2)$$

From Eq. 2, it can be found that droplets will have a higher apparent contact angle if less area is in contact with the solid substrate. The CB equation simply indicates the contact angle can be increased even when the intrinsic contact angle of a liquid on the original smooth surface is less than 90° .

New developments in the field show that there may need to be taken other considerations for contact angles and contact angle hysteresis. It is suggested that the contact line model is a better approach to predict the superhydrophobicity of surfaces (Gao and McCarthy 2007, 2009) (Fig. 1).

Casting

Francesco Galiano

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Casting is the main technique applied for the preparation of flat polymeric membranes using phase inversion process (such as NIPS, VIPS, etc.). The procedure for casting flat sheet membranes can be summarized as follows:

1. Preparing the casting solution by dissolving the polymer in the appropriate solvent
2. Placing a suitable casting plate (a belt, a glass, or other supports)
3. Adjusting the desired casting knife thickness
4. Pouring the polymeric solution on the casting plate
5. Uniformly spreading out the polymeric solution across the casting plate (Fig. 1)

Then, based on the way the phase separation occurs, the following techniques can be distinguished:

- Wet-casting process: the cast film is immersed into a coagulation bath, and due to solvent/nonsolvent exchange, the precipitation of the polymer occurs.
- Dry-casting process: the volatile solvent is left to evaporate from the cast film leading to the precipitation of the polymer.

Casting, Fig. 1 Procedure for casting flat sheet membranes at lab scale and methods for inducing phase separation

- Dry-wet-casting process: the cast film is exposed to a nonsolvent vapor (generally water) for a fixed time and then immersed into a coagulation bath.
- Thermal-induced phase separation: the cast polymer solution prepared at elevated temperature is cooled down causing phase separation and polymer precipitation (Drioli and Giorno 2009).

Manual and automatic casting machines are used both at laboratory and at industrial scale. In the latter case, the casting machine is on purpose created for specific applications. Commercial membranes are, usually, cast on porous supports made up, for instance, of a nonwoven polyester material in order to improve their mechanical stability, obtaining composite membranes.

Casting Solution

Francesco Galiano

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Casting solution is used to prepare membranes by casting method. Polymer and solvent are the main components of the solution system, but various additives can be also added. The choice of the polymer is of primary importance in preparing the casting solution. The polymer, in fact, must be soluble in the selected solvent in an appropriate concentration which is strictly related to final membrane application. Low concentrations of polymer, in fact, generally lead to a membrane with a porous structure, while high concentrations of polymer produce membranes with a more dense structure. The typical solution casting, with a polymer concentration ranging from 15 to

20 wt.%, is used for the preparation of porous ultrafiltration membranes. On the contrary, a solution casting containing higher concentrations of polymer, up to 25 wt.%, is used for the preparation of reverse osmosis, gas separation, and pervaporation membranes.

Even the choice of the solvent is not arbitrary but based on specific requirements. The solvent must dissolve the polymer, and it must be miscible with a nonsolvent, when it is used as coagulation medium, taking into account both kinetic and thermodynamic aspects. Due to the fast demixing in water, aprotic solvents, such as dimethyl formamide, dimethyl acetamide, or dimethyl sulfoxide, are preferred if membranes with a porous and asymmetric structures have to be obtained. On the contrary, solvents causing a slow precipitation of the polymer, such as acetone or tetrahydrofuran, are used for the production of dense membranes.

Addition of various modifiers in the solution casting allows to adjust membrane properties on the basis of final membrane application. Cosolvents, nonsolvents, and fillers of different types, such as pore forming and cross-linking agents, can be added to the casting solution (Drioli and Giorno 2009). Although these additives are used in low concentrations, they are determinant for the final membrane performances and applications.

Casting Solution Additives

Silvia Simone

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

A casting solution is normally prepared to be filmed as a flat sheet, or extruded as a hollow

fiber, in polymeric membrane preparation via phase inversion. The two main components of a casting solution are the selected polymer (P) and a suitable solvent (S) (or a diluent, for membrane preparation via TIPS). Different types of additives can be introduced in the casting solution composition to improve/enhance some selected membrane properties, depending on the application. Additives can be divided in two categories: soluble and insoluble additives. Soluble additives can be, in general, salts, as LiCl and LiClO₄; small molecules, as glycerol or ethylene glycol (EG); or polymers, as polyethylene glycol (PEG) or polyvinyl pyrrolidone (PVP), with different molecular weights (Mw). Most soluble additives are introduced to enhance the formation of membrane pores and are called “pore former” or “pore forming.” They are normally leached out from the membrane matrix in the coagulation bath. However, high Mw additives, as PVP, can be retained in the membrane structure. This effect can be exploited to tailor membrane wettability, since PVP is hydrophilic. Similarly, a class of poly(ethylene oxide)-b-poly(propylene oxide)-bpoly(ethylene oxide) triblock copolymers, referred to as Pluronic[®], can be used as additives to improve membrane hydrophilicity, thanks to their stable incorporation in the polymeric matrix. The effect of soluble additives on the membrane morphology depends on a trade-off between thermodynamic and kinetic factors. Soluble additives can increase the thermodynamic instability of the casting solution. This can be detected from a shift of the binodal curve toward the P/S axis, in ternary phase diagrams, which indicates less non-solvent (NS) tolerance of the P/S/Additive system, with respect to the P/S system having the same polymer concentration. This normally promotes phase inversion, resulting in more porous structures, and may enhance macrovoids formation as well. However, additives can also increase the dope viscosity. This will hinder the S/NS exchange and, hence, delay phase inversion. As a result, membrane structure can shift to more spongy type, while macrovoids formation may be reduced. For instance, PVP affects both the thermodynamic and kinetic of the phase-inversion process due to its hydrophilicity and

its effect on the dope viscosity (Simone et al. 2010). Hence, the effect of PVP on the final membrane morphology and properties depends both on its concentration and molecular weight. On the one hand, PVP concentration is directly connected with the thermodynamic of the P/S/Additive/NS system. On the other hand, the casting solution viscosity increases with polymer concentration and molecular weight. Finally, the additive leaching from the polymeric matrix is more difficult as its Mw increases. Several examples of casting solution soluble additives effect on membrane morphology and properties can be found in literature. For instance, the analysis of PVP effect on the kinetic and thermodynamic of phase inversion during preparation of polysulfone (PS) membranes was carried out by Lee et al. (2003). Mansourizadeh et al. (2010) found that lithium chloride acted as a phase-inversion promoter additive and was leached out in the coagulation bath in the preparation of poly(vinylidene fluoride) (PVDF) hollow fiber membranes. This resulted in fibers with reduced pore size, high surface porosity, and low mass transfer resistance.

Susanto et al. (2009) reported that Pluronic[®] improved the wettability of polyethersulfone (PES) membranes, thanks to its amphiphilic, surfactant properties, and was stably integrated in the membrane matrix. Other relevant examples for each additive type can be found in the review by Guillen et al. (2011).

Insoluble additives can be also used to tailor certain membrane properties. Inorganic fillers, as zeolites, metal oxides (as TiO₂, ZnO, Al₂O₃), hydrophobic/hydrophilic cloisite, and carbon-based fillers (graphene oxide, nanotubes, fullerenes), can be incorporated, usually as powders of nanometric size, in the casting solution, for preparing mixed-matrix membranes (MMM). In this case, filler stability in the membrane matrix, as well as its uniform dispersion, is among the key issues. For example, TiO₂ nanoparticles (NPs) show photocatalytic, antibacterial, antifouling, and UV-cleaning properties. They can be introduced in the membrane matrix to enhance

wettability and endow membranes with self-cleaning, antifouling, and antibacterial properties (see, for instance, the work by Song et al. 2012). Zeolites and carbon-based fillers can be used to overcome the typical trade-off between membrane productivity and selectivity in different applications, as gas separation and pervaporation (see Clarizia et al. 2004; Vu et al. 2003; Dobrak et al. 2010). Other insoluble additives, as silica particles, can be etched out, using proper acid/alkaline treatment, and work as pore formers (Hashim et al. 2011).

Catalyst Entrapment

Ivo Vankelecom

Centre for Surface Chemistry and Catalysis, KU Leuven, Leuven, Heverlee, Belgium

Catalyst entrapment refers in a membrane context to the confinement of a catalyst in a membrane. The catalyst can be either a homogeneous or heterogeneous catalyst, or an enzyme. Two basic ways exist for the entrapment. In the first approach, the (bio)catalyst is dispersed or dissolved in the polymer solution, which after forming into a flat-sheet or hollow-fiber membrane can be turned into a dense or porous catalytic membrane. If of a porous nature, the pore sizes should obviously be smaller than the (bio)catalyst to prevent leaching. If of a dense nature, steric occlusion can also help to retain the catalyst inside the polymer, but this will also happen when the affinity for the polymer matrix is much higher than for the reaction mixture, hence prohibiting catalyst dissolution in the contacting reaction fluid (Vankelecom 2002). In the second approach, encapsulation can be applied (McMorn and Hutchings 2004). Confinement of a liquid which contains the (bio)catalyst is then taking place within small capsules enclosed by a polymer or a surfactant.

Catalyst Immobilization in Membranes

Ivo Vankelecom

Centre for Surface Chemistry and Catalysis, KU Leuven, Leuven, Heverlee, Belgium

By incorporating catalysts in membranes, a new environment is created around the catalyst which can in several ways influence the catalytic activity and selectivity of the catalyst. The membrane can block certain inhibiting compounds from the catalyst surroundings by steric exclusion or by decreasing the sorption tendency of that compound and/or its diffusion to the catalyst. Alternatively, it can facilitate the transport of desired compounds to the reactive sites. When incorporated in a membrane, other reactor setups can become available, e.g., with the two reagents contacting the membrane (and thus the immobilized catalyst) from the different sides.

Different methodologies exist to immobilize homogeneous catalysts in membranes: via a covalent or coordinative bond between the catalyst and the membrane, via electrostatic interactions between them, through steric occlusion of the catalyst in a matrix or through physical adsorption of the catalyst on the membrane surface or in its pores. For homogeneous catalysts in specific, extra advantages appear upon immobilization in a membrane. This can be in fact a strategy to heterogenize the catalyst; it allows good dispersion of the homogeneous catalyst into the reaction environment and finally also offers an easy way for reuse. Additives that boost the catalyst performance can also be co-immobilized. On the other hand, leaching of the catalyst or these additives from the membrane can be a problem under certain liquid-phase reaction conditions.

When heterogeneous catalysts are immobilized in polymeric membranes, this is most commonly done by dispersing them in

the membrane casting solution. Key is then to find a good solvent for the polymer that initially allows creation of a good dispersion of the heterogeneous catalyst and that is subsequently evaporated fast enough to avoid settling of the catalyst particles, leaving an even membrane behind.

Catalyst Loading

Ivo Vankelecom

Centre for Surface Chemistry and Catalysis, KU Leuven, Leuven, Heverlee, Belgium

The term “catalyst loading” refers to the amount of catalyst present in a catalytic membrane, most commonly expressed as mol/g or g/g.

If the catalyst is incorporated in the membrane already during the membrane preparation (in contrast to a post-synthesis catalyst deposition), dispersion problems can appear, especially at higher loadings. This can be reflected in aggregate formation for heterogeneous catalysts and in cluster formation or even precipitation for homogeneous catalysts. When the catalyst is present during membrane preparation, side effects might complicate the preparation of the catalytic membrane, such as interference of the catalyst with the solvent evaporation or the polymer curing or settling of the catalyst.

Catalyst Retention by Membranes

Ivo Vankelecom

Centre for Surface Chemistry and Catalysis, KU Leuven, Leuven, Heverlee, Belgium

When coupling catalysis to membrane separations, the catalyst retention expresses in general the amount of catalyst that does not pass the membrane while filtering the reaction mixture over a membrane. Such mixture can either contain a homogeneous or heterogeneous catalyst. The membrane used to retain it will then need to have a pore size able to retain the dissolved/dispersed catalyst by size. If dense membrane is applied, good retention can also be realized by lowering the affinity of the membrane material for the catalyst or the diffusion of the catalyst through it. The filtration can be driven by a variety of driving forces (pressure, concentration, electrical, thermal), depending on the reaction type that is run and the conditions under which the reaction is taking place. The separation can run at the same time as the reaction in a continuous hybrid process, or the removal of the catalyst can take place batchwise. In the latter case, the conditions for the separation can be different from the conditions during reactions; hence, both can be optimized separately (Vankelecom 2002).

Retention and rejection by a membrane refer to the same effect of withholding a compound by a membrane, but by definition, retention refers to a concentration of the removed compound in the feed, while rejection refers to the concentration in the retentate (Mulder 1991). In continuous processes or when using large feed volumes from which only small quantities are filtered, both definitions become equal.

Many of such membrane-assisted catalytic reactions have been described, where the membrane separation process is either pervaporation (very popular to shift the equilibrium of the reaction to the right by removing the products of the

reaction), vapor permeation, gas separation, ultrafiltration (solvent resistant), nanofiltration, reverse osmosis, or dialysis. They all aim at an easy recovery of the catalyst or at operating in continuous or semi-batch mode. A very high catalyst retention is required, since the continuous loss of small amounts of catalyst adds up seriously after treating several batches or in a long-term continuous process (Brinkmann et al. 1999). Tricks to increase the catalyst retention can be to enlarge the catalyst by creating polymeric, dendrimeric, or hyperbranched versions of the homogeneous catalysts (Van Koten et al. 2002; Muller et al. 2005).

Catalytic (Pt-Y) Membranes

Catia Algieri

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Today, about the 60–70 % of hydrogen is produced by steam reforming. The reaction products

are a mixture of CO and H₂. Additional hydrogen can be recovered by a lower-temperature gas-shift reaction. At the end of this process, the amount of carbon monoxide is equal to 1 %. This CO amount is not tolerated by the PEM fuel cells. In order to avoid cell performance degradation, carbon monoxide concentration must be kept below 10 ppm in the hydrogen feed streams (Rohland and Plzak 1999); CO selective oxidation (selox) is an interesting and economic approach for a deep purification of H₂-rich gas streams from carbon monoxide (Avgouropoulos and Ioannides 2003). During this process two competitive reactions take place, carbon monoxide and hydrogen oxidation, and so a selective catalyst is required to avoid hydrogen consumption. Among the various catalysts used, the better is the platinum because it represents a good compromise between cost and performance. It demonstrated the possibility to use Pt-Y membranes as innovative devices to perform the CO selective oxidation (Hasegawa et al. 2002). These systems permit to disperse catalytic nano-sized particles in a thin zeolite layer assuring a good contact between reactants and catalytic sites and at the same time a low pressure drop and reduced bypass (Fig. 1).

Catalytic zeolite membrane Pt-loaded demonstrated the possibility to reduce the CO concentration from 10,000 ppm down to 10–50 ppm (Bernardo et al. 2006, 2008). The membrane with the best permeation properties exhibited the best catalytic performance (amount of CO at the outlet stream equal to 10 ppm). A negligible effect of the feed pressure was obtained with the low-permeance membranes. On the contrary,

Catalytic (Pt-Y) Membranes,

Fig. 1 Scheme of a catalytic zeolite membrane reactor

positive effect was found by using more permeable membranes. The effect of the pressure on CO conversion can be explained considering two different paths for the reactants: through the zeolite channels (first path) and defects (second path). CO molecules permeating into the zeolite channels interact with the catalyst (Pt) with very high probability owing to the narrow space of the zeolite pores. In this case, the effect of pressure is negligible on the conversion. On the contrary, the interaction of the CO molecules with the catalyst depends on the pressure owing to the large volume of the support pores.

- aluminum (Szostak 1998). The resulting structure is very regular with pore size at molecular scale. Their adsorption properties change varying the Si/Al ratio during the synthesis because it determines the number of cations in the structure and so their hydrophilicity (Szostak 1998). When the cation is a proton, a Brønsted acid site is formed in the zeolite structure (Abott and Guerzoni 1992). In addition, different transition metals can be loaded (by cationic exchange) into the zeolite channels (Howe 2004). These inorganic crystals are used at industrial level as adsorbents for the purification and separation of different substances and as exchangers in laundry detergents (Smulders et al. 2003). Furthermore, they are largely used as catalysts (Weitkamp 2000). In catalysis, the best performances of the zeolite with respect to the other systems are the high concentration of acid sites and their high thermal and hydrothermal stability. Besides, their shape selectivity plays a very important role to orient the reaction toward the production of the desired product (Chen et al. 1989). They are used in different acid-catalyzed hydrocarbon transformations such as cracking, isomerization, and alkylation which are very important reactions in the petrochemical industry, and increasing attention is also focused in environmental catalysis and synthesis of fine chemicals (Xu et al. 2006). The oldest and largest application of the catalytic zeolites in oil refining is the fluid catalytic cracking (Martinez and Corma 2011). Hydrocracking is the second largest application of zeolite in this field. In this last process, zeolites are used for their high stability toward the deactivation by coking or by nitrogen compounds (Ward 1993). In the petrochemical process, very relevant is the production of the most important isomer of the xylene (para-xylene) because it is used for the production of terephthalic acid that in turn is used for the synthesis of polyester resin and fibers. This process is carried out by using ZSM-5 zeolite taking advantage of its shape selectivity property and low coking tendency (Corma et al. 2011). A further development of zeolite chemistry (e.g., synthesis of structures with more large pores) will open new possibilities for processes in chemical, fine chemical, and biomass transformations.

Catalytic Membranes

Jose M. Sousa

Chemistry Department, School of Life and Environment Sciences, University of Tras-os-Montes e Alto Douro, Vila Real, Portugal

LEPABE–Laboratory for Process Engineering, Environment, Biotechnology and Energy, Chemical Engineering Department, Faculty of Engineering, University of Porto, Rua Roberto Frias, Porto, Portugal

A catalytic membrane is a membrane with catalytic properties. The catalytic activity can be intrinsic to the material itself, as in the case of membranes made of Pd, TiO₂, and H-ZSM-5 zeolite, which are catalytic for specific reactions, or can be obtained by coating the external or the internal (porous) surfaces of the membrane with the catalyst (metal or oxides) or even by occluding the catalyst (metal nanoclusters, zeolites, activated carbon, metal complexes) inside a dense polymer matrix (Gryaznov 1986, 1992; Irusta et al. 1998; Gobina and Hughes 1994; Saracco and Specchia 2000; Itoh 2000; Dittmeyer et al. 2001; Piera et al. 2001; Julbe 2005; van Dyk et al. 2003; Marcano and Tsotsis 2002; Basile 2012; Fritsch and Peinemann 1995).

Catalytic membranes can be inorganic (metallic, ceramic, or carbon made) or polymeric in their nature. Examples of dense inorganic catalytic membranes are the ones made of palladium, which are catalytically active for hydrogenation reactions (though presenting low activity), while porous catalytic inorganic membranes can be made of a variety of materials, namely, alumina, silica, titania, and zeolites among others. Porous polymeric membranes are usually made, for example, of polysulfone, polyacrylonitrile, or polypropylene, while dense polymeric membranes are prepared from PDMS (polydimethylsiloxane) and other silicones, PVA (polyvinyl alcohol), perfluoropolymers, polyimides, or polyamides among other polymers (Basile and Gallucci 2011; Basile 2012).

Membranes in general can be permselective or nonpermselective. Catalytic permselective membranes are characterized by two important parameters concerning their separation ability: Permselectivity, which describes the ability of the membrane to transport the different components of a mixture at different rates, and the permeability, which quantifies the total amount permeated by the membrane when subjected to specific operation conditions. Nonpermselective membranes can be described by their permeability, but they are not able to discriminate between the different components of a mixture (Marcano and Tsotsis 2002).

The mass transport mechanism suitable to describe the permeation rate through a (catalytic) membrane is primarily a function of the type of membrane. For dense membranes, the accepted model is the sorption (solution) diffusion (the permeant species in gas or liquid phase sorbs into the membrane at the higher chemical potential side, diffuses through the membrane subjected to the driving force gradient, and desorbs on the opposite side). These membranes are usually permselective. Concerning porous membranes, the total mass transport results from different contributions, namely, a diffusive component (activated, surface, Knudsen and bulk) and a viscous component (Poiseuille flow). The contribution of each one depends on the operating conditions and on the pore's size. For pore radius between 1 and 50 nm, Knudsen diffusion is normally the predominant mass transfer mechanism (Knudsen diffusion is characterized by the mean-free path of the traveling species being much larger than the pore radius and is independent of any pressure gradient along the pore), and the membranes present some permselectivity, related with the ratio of the species molar mass. For membranes with larger pores, namely, macroporous, the mass transfer mechanism is a viscous flow if a total pressure gradient across the porous membrane is present or bulk diffusion if not. Neither of these situations allows any permselectivity. When the membrane has micropores and the species adsorb significantly, as in

the case of zeolites, surface diffusion has a relevant contribution. Also in these cases the membranes are permselective (Basile and Nunes 2011).

A catalytic membrane is used to carry out different types of reactions, namely, chemical, biochemical, electrochemical, or photocatalytic, in a so-called membrane reactor. The type of membrane to be used, porous or dense, polymeric or inorganic, etc., depends on several factors, namely, the type of reaction. For example, dense polymeric catalytic membranes are used for low-temperature reactions where the permselectivity is important for shifting the conversion beyond the thermodynamic equilibrium value based on feed conditions (e.g., selective removal of water in esterification reactions) or to enhance the reaction selectivity (e.g., hydration, epoxidation, isomerization, and hydrogenation reactions). Dense polymeric catalytic membranes can also be used as contactors for promoting reactions between two immiscible phases with segregated feed (e.g., oxyfunctionalization of hydrocarbons with hydrogen peroxide reactions) (Basile and Gallucci 2009).

Another type of reaction that has been studied is the photocatalytic removal of contaminants from water, either using porous or dense polymeric catalytic membranes. The catalyst typically used is TiO_2 , occluded or coated, but also occluded Fe in an H_2O_2 oxidant medium (photo-Fenton process) has been considered (Basile and Nunes 2011).

Catalytic nonpermselective porous membranes, polymeric or inorganic, can be used to improve the contact between the reactants and the catalyst, in order to obtain higher reaction conversions. Particularly in the case of triphasic (gas/liquid/solid) reactions, usually limited by the diffusion of the gaseous reactant, porous membrane reactors show conversion advantages. By controlling the pressure of the gas and liquid flows, it is possible to shift the reactants to meet the catalyst zone (Fig. 1).

The same segregated feeding strategy can also be used in cases of reactions where a strict control

Catalytic Membranes,

Fig. 1 Porous catalytic membrane for wastewater treatment (Reprinted with permission from Raeder 2010)

of the reactants is important, namely, in the case of very fast or highly exothermic reactions. In the case of reactions where a complete conversion of some components, like VOCs, is of high importance, porous catalytic membranes, permselective or not, are usually used in a “flow-through” mode, that is, all the reactants are fed conjointly. In these cases, it is critical controlling the residence time of the reactants to guarantee a complete conversion (Westermann and Melin 2009).

Catalytic Methanol Steam Reforming

G. Kolb

Product Sector Energy and Chemistry, Fraunhofer ICT-IMM, Mainz, Germany

Methanol receives increasing interest as future energy carrier for distributed and mobile power generation, because it can be produced via sustainable routes and has a high storage stability and energy density when compared with liquefied or compressed hydrogen. When treated by reforming technology, it serves as a hydrogen source for fuel cells (Kolb 2008).

Methanol is converted to hydrogen-containing reformat by endothermic steam reforming (STR) (Kolb 2008) as shown in Eq. 1:

The highest hydrogen concentration in the reformer product is achieved at S/C 1. In order to reduce the carbon monoxide formation and to avoid coke deposition on the catalyst, a

surplus of steam is required. Therefore, practical systems operate at S/C ratios between 1.3 and 2.0. Because an excess of steam is required to maintain catalyst durability, apart from hydrogen and carbon dioxide, the reformat contains significant amounts of unconverted steam and to a lower extent some unconverted methanol and carbon monoxide. The latter is (at least for conventional Cu/ZnO catalysts) formed by the reverse water-gas shift reaction as shown in Eq. 2 (Fig. 1):

When not only steam but also air is fed to the reformer, the reaction is named oxidative methanol steam reforming:

S/C is the molar steam to carbon (here methanol) ratio; O/C is the ratio of atomic oxygen in the

Catalytic Methanol Steam Reforming,

Fig. 1 Equilibrium gas composition of methanol steam reforming vs. S/C ratio of the feed; pressure 5 bar; temperature 200 °C (Schmidt et al. 1994)

oxidant to carbon in the fuel. The hydrogen content in the reformat is then derived from the following equation:

$$x(\text{H}_2) = (3 - (\text{O/C})) / (3 + (\text{S/C}) + 0.5(79/21)(\text{O/C})) \quad (4)$$

Oxidative steam reforming involves also the exothermic partial oxidation of methanol:

The enthalpy of the reaction at a temperature T is:

$$\begin{aligned} \Delta H_{298}^0 &= (1 - (\text{O/C}))\Delta H_R^T(\text{STR}) \\ &+ (\text{O/C})\Delta H_R^T(\text{POx}) \end{aligned} \quad (6)$$

For oxidative steam reforming with $\text{S/C} = 1.5$ and $\text{O/C} = 0.2$ at 350°C reaction temperature, the wet reformat has a hydrogen content of 57.4 Vol.%, and the reaction enthalpy amounts to 15 kJ/mol, i.e., the reaction is still endothermic. Heat losses are not included into the calculations above which means that additional energy is required to compensate for. In a practical, self-sustaining reactor, this energy could be gained from additional oxygen supply to the feed or by separate or integrated anode off-gas combustion.

Frequently observed by-products of methanol steam reforming are formic acid and methyl formate (HCOOCH_3), which are not tolerated by the anode electrocatalyst of low-temperature PEM fuel cells. They are intermediate products of methanol steam reforming (Takahashi et al. 1985):

Formic acid decomposition is a fast reaction (Jiang et al. 1993). Dimethyl ether is formed by

methanol dehydration and is also observed as a by-product:

The reaction is thermodynamically favored by lower reaction temperatures (Lwin et al. 2000).

Catalyst development for methanol steam reforming as hydrogen source for fuel cells had been mainly focused on ZnO-containing catalysts such as Cu/ZnO and Pd/ZnO (either supported by the ZnO itself or by alumina carrier) owing to their high activity and low selectivity toward carbon monoxide. However, these catalyst formulations show a number of drawbacks. Once converted into their active (reduced) state, Cu/ZnO catalysts show pyrophoricity when exposed to an oxidizing environment. At reaction temperatures exceeding 300°C , the catalyst deactivates, which originates from copper sintering. Cu/ZnO is an excellent water-gas shift catalyst, which is its current main industrial application field. Consequently, carbon monoxide is formed by the reverse water-gas shift reaction as soon as all the methanol is converted, which happens under conditions of partial load of a practical reformer reactor. Pd/ZnO catalysts are higher in activity when compared to Cu/ZnO, mainly because this catalyst type allows higher operating temperature. Even at reaction temperatures exceeding 300°C , the selectivity toward carbon monoxide remains low, because a Pd/Zn alloy is formed (Chin et al. 2002, 2003). However, Pd/ZnO catalysts are known to bear always the risk of metallic palladium formation, which results in carbon monoxide formation much higher than the values formed over Cu/ZnO or Pd/Zn alloy. Pd/ $\text{In}_2\text{O}_3/\text{Al}_2\text{O}_3$ and Pt/ $\text{In}_2\text{O}_3/\text{Al}_2\text{O}_3$ catalysts are an alternative to the catalysts discussed above (Men et al. 2010; Kolb et al. 2011). They are even more active than Pd/ZnO.

Catalytic Reactions, Membrane Operations of

Adelio Mendes

Faculty of Engineering, University of Porto,
Porto, Portugal

Catalytic reactions (chemical, biochemical, photochemical, electrochemical, and photoelectrochemical) are promoted or enhanced in their rate by a catalyst. Most of the chemical catalytic reactions are heterogeneous; the catalyst is normally a solid, while reactants are in fluid phase. In the petrochemical industry, for example, the catalyst is usually composed of micro- or nanoclusters of a noble metal in a support, usually a metal oxide. In the fine chemical and organic synthesis, on the other hand, it is common that the reactions be homogeneous.

Membrane is a permselective medium or interface between two fluid phases. Membrane

processes can be synergistically combined with catalytic reactors targeting conversion, selectivity, or safety enhancements. These effects may be obtained by selective product extraction and purification, normally originating conversion and selectivity enhancements, or by segregated or distributed feed of reactants, aiming selectivity and/or safety enhancements. When a reactor is synergistically combined with a membrane process, the unit is called membrane reactor. Usually, membrane and reactor are integrated in the same housing (Marcano and Tsotsis 2002).

Membranes can be inorganic (metallic, ceramic, carbon) or polymeric in their nature. Membranes can be permselective or non-permselective. Permselective membranes are characterized by two important parameters: permselectivity, which describes the ability of the membrane to transport the different components of a mixture at different rates, and permeability, which quantifies the total amount permeated by the membrane when subjected to specific operation conditions, normalized by the membrane thickness. The mass transport mechanism is described by the sorption – diffusion models for dense and microporous membranes. For porous, different contributions should be considered: diffusive (activated, surface, Knudsen, and bulk) and viscous (Poiseuille flow). The contribution of each one depends on the operating conditions, pore size, penetrant mass and size and the surface, and penetrant nature (Basile and Gallucci 2011).

There are various potential industrial applications that take advantage of combining a catalytic reactor with a membrane process, integrated or not in the same device, operating either in liquid and/or gas phases. One of the main membrane studied functions has been the selective removal of components from the reaction medium. Biorefining and biofuel production, for example, take advantage of process integration of a bioreactor and a permselective membrane, as is the case of bioethanol and acetic acid production: the continuous removal of the main product from the reaction medium decreases or even eliminates the potential reaction inhibition (Ma et al. 2009;

He et al. 2012). Also the removal of fermentation inhibitors generated during the pretreatment process of lignocellulosic material for the second-generation bioethanol production is important, because of the negative impact in the ethanol yield and productivity and in the cell growth inhibition (He et al. 2012). Still in the selective removal of a reaction product from the reaction medium, it can be referred to as the selective removal of water in esterification reactions and the selective removal of hydrogen in dehydrogenation and water-gas shift reactions for a conversion shifting beyond the thermodynamic equilibrium based on feed conditions. In case of using palladium-silver membranes in the dehydrogenation and water-gas shift reactions, high-purity hydrogen can be obtained (Marcano and Tsotsis 2002; Basile and Nunes 2011).

The membrane can also play a role of a selective distributor, dosing a reactant along the reaction medium. This approach has been extensively used in consecutive-parallel reaction schemes, especially in partial oxy-dehydrogenation or oxidation of alkanes and oxidative coupling of methane, using dense ceramic or metallic membranes permselective to oxygen (silver, yttrium-stabilized zirconia, perovskites and related oxides, or composite membranes involving a mixture of ionic and electronic conducting materials, usually oxides and metals). Separating the hydrocarbon and oxygen feed, the reaction is carried on in much safer conditions, and the possibility of thermal optimization and oxygen concentration control along the reaction medium can be used to improve the selectivity for the intermediate desired oxygenated product. Though in less extension, also proton-conducting membranes have been considered as distributors for hydrogenation reactions (Marcano and Tsotsis 2002; Seidel-Morgenstern 2010).

Catalytic Reformer Off-Gas

G. Kolb

Product Sector Energy and Chemistry, Fraunhofer ICT-IMM, Mainz, Germany

The product mixture formed during reforming of all kind of fuels such as hydrocarbons and alcohols is named reformat (Kolb 2008). The products of the reforming reaction are hydrogen and carbon monoxide (see entry “► Catalytic Reforming of Methane and Other Hydrocarbons”) unless methanol is applied as feed, which produces mainly carbon dioxide instead. The thermodynamic equilibrium of the reforming reaction itself is equivalent to full conversion of all kinds of fuels except for methane. The conversion of methane is limited by the equilibrium of the methanation reaction, which is the reverse reaction of methane steam reforming:

$$\Delta H_R = -253.7 \frac{kJ}{mol} \quad (1)$$

Catalytic Reformer

Off-Gas, Fig. 1 Dry reformat composition of isooctane partial oxidation in the presence of steam (nitrogen excluded); S/C = 3.0; O/C = 1.0; GHSV = 8,776 h⁻¹ (Moon et al. 2001)

The formation of methane is favored by lower temperature and elevated pressure, and therefore usually reformat from higher hydrocarbon reforming contains some methane (see Fig. 1). Methane is tolerated by most fuel cell types up to a concentration of 5 vol.%. Over sufficiently active catalyst and at reaction temperatures exceeding 600 °C, a second reaction occurs up to its thermodynamic equilibrium, the water-gas shift reaction:

The thermodynamic equilibrium of the reaction is favored by lower temperature (see Fig. 1).

Reformat contains besides hydrogen and carbon monoxide, depending on type of reforming applied, in case of steam reforming unconverted steam and for partial oxidation significant amounts of nitrogen originating from the air feed. Reformat originating from autothermal reformers contains both unconverted steam and nitrogen because both steam and air are fed to the process.

In case the reformat is dedicated as hydrogen supply for PEM fuel cells, the carbon monoxide content has to be minimized. The situation is different, when high temperature fuel cells such as SOFC are applied, because they are capable of converting carbon monoxide.

Further undesired by-products, which are frequently found in reformat originating from alcohol fuels, are acetaldehyde, ethers such as dimethyl ether and acetone. Light hydrocarbons, namely, ethylene and propylene, are frequent by-products of higher hydrocarbon reforming and an indicator for catalyst activity losses which then result in release of unconverted fuel later on.

Unconverted fuel and by-products are undesired components in reformat because they cannot be converted by fuel cells and reduce the efficiency of the energy conversion process. On top of that, they also poison the fuel cell catalyst in most cases.

Because hydrocarbon fuels frequently contain sulfur components, which originate from intended odorant addition in the case of gaseous fuels such as natural gas (methane) and liquefied petroleum gas (LPG, propane/butane) and from the sulfur species present in the crude oil for higher

hydrocarbons, a sulfur removal is required when fuel cells are connected to the reformer. While gaseous fuels can be relatively easily purified through adsorption processes, sulfur removal from liquid fuels is more complicated, mostly owing to the lower adsorption capacity in the liquid phase. Because the reforming catalyst itself is normally rather sulfur tolerant and converts sulfur species to hydrogen sulfide, the sulfur removal can be performed through conversion over zinc oxide in the gas phase downstream the reformer:

To convert the carbon monoxide which is poisoning for low-temperature PEM fuel cells to carbon dioxide, the water-gas shift reaction (see Eq. 2) is applied in dedicated reactors downstream the reformer, which operate at lower temperature to shift the equilibrium of the reaction.

To reach the low concentration of carbon monoxide required for low-temperature PEM fuel cells, which is in the range between 10 and 100 ppm, preferential oxidation (see Eq. 4) or selective methanation reactions (see Eq. 1) are applied:

The preferential oxidation reaction is accompanied by the undesired side reaction of part of the hydrogen present in the reaction mixture:

Usually preferential oxidation requires a minimum of excess air corresponding to an atomic oxygen to carbon monoxide O/CO ratio between 1.5 and 2.0. Under these conditions and full conversion of carbon monoxide, between 0.5 and 1.0 mol of hydrogen is lost for each mole carbon monoxide converted.

Catalytic Reforming of Methane and Other Hydrocarbons

G. Kolb

Product Sector Energy and Chemistry, Fraunhofer ICT-IMM, Mainz, Germany

Reforming of hydrocarbons is possible by conversion with either oxygen from air (partial oxidation), steam, or a combination of both named oxidative steam reforming. Only in the case of a self-sustaining operation of an oxidative steam reformer, when the partial oxidation reaction produces sufficient heat for preheating the feed, supply of the endothermic steam reforming with energy, and compensation of the heat losses of the reactor to the environment, this process should be named autothermal reforming (Kolb 2008).

The general formula of hydrocarbon steam reforming is provided below:

The product mixture of the endothermic reaction is named reformat, which contains besides hydrogen and carbon monoxide some unconverted steam, possibly unconverted fuel and carbon dioxide, which is formed through consecutive water-gas shift:

Catalytic Reforming of Methane and Other Hydrocarbons,

Fig. 1 Equilibrium conversion of methane steam reforming versus reaction temperature for different S/C ratios and system pressure (Joensen and Rostrup-Nielsen 2002)

This reaction obviously increases the hydrogen concentration of the reformat. Under operating conditions of hydrocarbon steam reforming over sufficiently active catalyst, thermodynamic equilibrium of water-gas shift is achieved.

Steam reforming of higher hydrocarbons shows also formation of methane through reverse methane steam reforming (methanation):

Increasing reaction temperatures and higher atomic steam to carbon (S/C) ratio increase the methane conversion according to the equilibrium of methane steam reforming reaction, while increasing system pressure has the opposite effect. The equilibrium conversion of methane steam reforming at various S/C ratio and system pressure is shown in Fig. 1. However, elevated pressure is required if the reforming process is combined with membrane separation and industrial steam reforming plants work at operating pressures exceeding 20 bar owing to similar

requirements of processes switched downstream the reformer.

While methane steam reforming is a reversible reaction, this is not the case for other hydrocarbon fuels.

Partial oxidation is the conversion of fuels to synthesis gas under oxygen deficient atmosphere:

The reaction is significantly faster than steam reforming. It requires only air feed and no water evaporation to raise steam, which simplifies the process. However, the carbon monoxide concentration is significantly higher compared to steam reforming, and the dilution through the nitrogen from the air is considerable. When hydrocarbons are converted by partial oxidation, some combustion occurs as an undesired side reaction (Joensen and Rostrup-Nielsen 2002), especially because an excess of air is fed into practical systems. The water produced by the combustion process allows water-gas shift to take place to a certain degree. Another typical by-product of partial oxidation

Catalytic Reforming of Methane and Other Hydrocarbons, Fig. 2 Ethylene formation versus time on stream for autothermal reforming of synthetic diesel (Kang et al. 2007)

is methane, which is formed according to reaction (3). Coke formation is a critical issue in partial oxidation. It is formed through the reaction of carbon monoxide with hydrogen, the Boudouard reaction, and cracking of higher hydrocarbons.

Figure 2 shows the breakthrough of unconverted fuel for oxidative steam reforming of synthetic diesel fuel. Catalyst deactivation during reforming of heavier hydrocarbons is indicated by the increasing formation of light hydrocarbons, predominantly ethylene. Yoon et al. (2009) explained the preferred ethylene formation in mixtures of paraffinic and aromatic feedstock by homogeneous decomposition of paraffinic components. The initial linear increase of the breakthrough is followed by an exponential increase later on.

Catalytic Wall Reactor

G. Kolb

Product Sector Energy and Chemistry, Fraunhofer ICT-IMM, Mainz, Germany

The micro-reactors discussed in the current section cover plate-heat-exchanger technology (see Fig. 1 (top)) with channels in the meso- and micro-scale, which are coated with catalyst in one or both flow paths, which makes them suitable for heterogeneously catalyzed reactions.

If only one flow path of the heat-exchanger is coated with catalyst, it transforms into a catalytic wall heater as shown in Fig. 1 (center). Catalytic

Catalytic Wall Reactor, Fig. 1 Threedifferent reactor concepts: conventional heater (*top*), catalytic wall heater (*center*), and catalytic wall reactor (*bottom*) (Redenius et al. 2001)

wall heaters improve the thermal management of exothermic reactions such as combustion and partial oxidation of fuels and of reactions related to CO removal from synthesis gas dedicated as hydrogen source for fuel cells, namely, water-gas shift and preferential oxidation of CO. Alternatively, endothermic reactions can be supplied with energy in such a reactor (catalytic wall cooler).

When the catalyst is coated onto the walls of the second flow path, the plate heat exchanger turns into a catalytic wall reactor as shown in Fig. 1 (bottom). This reactor type allows the direct coupling of exothermic reactions (such as steam reforming) and exothermic reactions (such as catalytic combustion). The heat source and the heat sink are then only separated by the few hundred to thousand micrometer metal foils between both catalyst coatings.

Micro-reactors for practical applications are chemical reactors carrying a multitude of channels with at least one dimension not exceeding one

millimeter. In such channels the flow regime is usually laminar, diffusion paths for heat and mass transfer are short, and the surface to volume ratio is small. Consequently surface effects dominate volumetric effects. Compared to macroscopic devices, a higher share of wall material exists. Thus the heat transfer through the wall material contributes significantly to the overall heat transfer and requires consideration when designing such reactors.

In practical micro-reactors suited for gas phase reactions, the channel dimensions are ranging between 250 μm and 1,000 μm height and from 250 μm to several millimeters width. Such micro-reactors carry normally thousands of channels operated in parallel. The high number and relatively large dimensions of the channels create a pressure drop in the order of few to few tens of mbar. The high degree of parallelization makes the scale up of such micro-reactors relatively simple provided that the equipartition of the fluid flow through all channels is ensured.

Obviously straight (micro-)channels are the simplest possible design. Other geometries such as sinusoidal channels or fin geometries have the potential for increasing the heat transfer. Increasing the heat transfer at constant pressure drop is not feasible for most channel geometries. Low pressure drop is critical for practical systems owing to the energy consumption required for the compression of gases.

A high heat conductivity of the heat-exchanger wall material reduces the efficiency of plate heat exchangers (Stief et al. 1999) especially if their length is similar to their width because isothermal temperature profiles will be created especially for construction material of high heat conductivity such as aluminum. It is therefore recommended to increase the heat-exchanger length and to reduce the wall material thickness and, if possible, to use construction material of low heat conductivity if a temperature profile is required in the catalytic wall reactor for reactions such as water-gas shift (Zalc and Löffler 2002; Baier and Kolb 2007).

However, heat-exchanger reactors for coupling exothermic and endothermic reactions such as catalytic combustion and steam reforming, respectively, should be operated under isothermal conditions. A cocurrent flow arrangement should

be chosen (Frauhammer et al. 1999) which has been proven for practical applications (Wichert et al. 2011; O'Connell et al. 2009).

The amount of catalyst which can be introduced into the plate-heat-exchanger reactor is a drawback more than counterbalanced by the better catalyst utilization through the improved heat and mass transfer. However, catalysts of higher activity are required to compensate the smaller quantities.

- as $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{Co}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$ (BSCF) and $\text{La}_{0.6}\text{Sr}_{0.4}\text{Co}_{0.2}\text{Fe}_{0.8}\text{O}_{3-\delta}$ (LSCF), as these materials show the highest oxygen flux.
- The mechanism of oxygen transport through the MIEC membranes involves three different steps (Fig. 1):
1. The oxygen dissociation and reduction on the membrane surface (interface I)
 2. The incorporation into the crystal lattice as oxygen anions and the migration through the lattice via oxygen vacancy defect sites
 3. The combination of the oxygen anions on the membrane sweep side (interface II)

Thus the oxygen permeation flux through a MIEC membrane is determined by the bulk diffusion across the membrane and the surface exchange reactions.

The bulk diffusion resistance of the material can be improved by reducing the membrane thickness. The resistance from bulk diffusion plays an important role when the membrane separation layer is relatively thick. The oxygen flux is proportional to the reciprocal of the membrane thickness. So the flux can be improved by decreasing the separation layer thickness. The membrane surface exchange reaction becomes the rate-limiting step when the thickness of the separation layer is decreased beyond a certain value (L_C). Then the oxygen flux can still be further increased by improving the surface exchange kinetics. This can be done by applying a porous layer of the membrane material itself to increase the surface area or by adding a catalytic coating of a material with enhanced oxygen exchange properties to the membrane surface.

An example of the first case is shown in Fig. 2 where a 10 μm thick porous layer of BSCF is shown on top of the dense separation layer. The extra surface area improved the oxygen flux of the membrane by 210 %.

Pd has better oxygen exchange properties than LSCF itself. So another strategy, performed by Yacou et al., is coating the membranes with Pd

Catalytically Modified (Activated) MIEC Membranes

Bart Michielsen and Marijke Jacobs
Sustainable Materials Management, Flemish
Institute for Technological Research – VITO,
Mol, Belgium

Dense ceramic membranes which are made from mixed ionic and electronic conducting (MIEC) oxides can selectively separate oxygen from air at temperatures above 700 °C. The most used MIEC membrane materials are perovskites, such

Catalytically Modified (Activated) MIEC Membranes,

Fig. 1 Different sections involved in oxygen transport during oxygen permeation (Sunarso et al. 2008)

Catalytically Modified (Activated) MIEC Membranes,

Fig. 2 Details of the morphology of the oxygen activation layer after the permeation test (Baumann et al. 2011)

Catalytically Modified (Activated) MIEC Membranes, Fig. 3 SEM micrographs of the surface of Pd modified LSCF membranes (Yacou et al. 2011)

Catalytically Modified (Activated) MIEC Membranes,

Fig. 4 Percentage improvement of the O₂ flux through some Pd modified LSCF membranes compared to the original LSCF membrane, as a function of the operating temperature (Yacou et al. 2011)

as shown in Fig. 3. This results in an even higher improvement ratio as shown in Fig. 4. This way the oxygen flux is improved by 350 %. So a small coating layer can have a big effect on the membrane oxygen flux without compromising the mechanical stability.

Cell Adhesion

Loredana De Bartolo

Institute on Membrane Technology, National Research Council, ITM-CNR, Rende, Italy

Cell adhesion is the binding of a cell to a surface, extracellular matrix (ECM), or another cell using

cell adhesion molecules, which are integral membrane proteins that have cytoplasmic, transmembrane, and extracellular domains. The extracellular domains of adhesion molecules extend from the cell and bind to other cells or matrix by binding to other adhesion molecules of the same type (homophilic binding), binding to other adhesion molecules of a different type (heterophilic binding), or binding to an intermediary “linker” which itself binds to other adhesion molecules. Adhesion molecules belong to four major families: cadherins, immunoglobulin-like adhesion molecules, integrins, and selectins. Cadherins cause adhesion via homophilic binding to other cadherins in a calcium-dependent manner. As is the case for their role in desmosomes and adherens junctions, cadherins ultimately anchor cells through cytoplasmic actin and intermediate filaments. Immunoglobulin-like adhesion molecules are involved in both homophilic and heterophilic binding.

The well-studied members of this group are the neural cell adhesion molecules (N-CAMs), which are expressed predominantly in nervous tissue, and the intercellular cell adhesion molecules (ICAMs). Integrins are a diverse and large group of heterodimeric glycoproteins. The two subunits,

designated as alpha and beta, both participate in binding. Integrins participate in cell–cell adhesion and are of great importance in binding and interactions of cells with components of the extracellular matrix such as fibronectin. Importantly, integrins facilitate “communication” between the cytoskeleton and extracellular matrix, allow each to influence the orientation and structure of the other. Selectins are expressed primarily on leukocytes and endothelial cells and, like integrins, are important in many host defense mechanisms involving those cells. In contrast to other cell adhesion molecules, selectins bind to carbohydrate ligands on cells, and the resulting binding forces are relatively weak. Cell adhesion is believed to be the first and dominant step for cell growth.

Cells adhere strongly to some materials, but not to others (Hynes 2002). This is determined by the special structure of individual cell membranes and material surface properties. The initial cellular events that take place at the biomaterials interface mimic to a certain extent the natural adhesive interaction of cells with the extracellular matrix (Griffin and Naughton 2002).

Cell adhesion on a substrate such as a membrane is a multistep process that involves, in sequence, adsorption of ECM proteins onto the surface, recognition of ECM components by cell receptors, cytoskeletal rearrangements, and cell spreading. In particular, immediately after the biomaterial comes into contact with cell environment, protein adsorption to its surface occurs. This happens within seconds, long before the first cells reach the surface. Consequently, cells almost never come into direct contact with the material surface; they rather interact with the layer of adsorbed proteins. This layer mediates the cell adhesion and also provides signals to the cell through the cell adhesion receptors. The membrane properties (roughness, physicochemical, mechanical, and transport) especially the surface characteristics play an important role in the adhesion process (De Bartolo et al. 2004, 2008). Surface free energy, electric charge, and morphology might all affect cell attachment and its behavior either indirectly, e.g., by controlling adsorption of the proteins present in the culture

medium (or secreted by the cells), or directly, e.g., by guiding cell spreading with suitable surface topography (De Bartolo et al. 2002). Such properties resulted in being critical to cell–substratum interaction and have to be considered in the choice of material suitable for biomedical device.

Cell Adhesion in Bioartificial Organs

Loredana De Bartolo

Institute on Membrane Technology, National Research Council, ITM-CNR, Rende, Italy

Binding of cells to a surface, extracellular matrix, or other cells in an artificial device is used to replace a nonfunctioning organ. Correct cellular adhesion is essential in maintaining multicellular structure and allows cells to interact dynamically with adjacent cells and the extracellular matrix. In bio artificial organs the cell adhesion process involves cell–cell and cell–natural or artificial matrix/material that plays essential roles in overall tissue architecture and proper physiological functions of the device.

The functional units of cell adhesion are typically multiprotein complexes made up of three general classes of proteins: the cell adhesion molecules/adhesion receptors, the extracellular matrix (ECM) proteins, and the cytoplasmic plaque/peripheral membrane proteins. The cell adhesion receptors are usually transmembrane glycoproteins that mediate binding interactions at the extracellular surface and determine the specificity of cell–cell and cell–ECM recognition. They include members of the integrin, cadherin, immunoglobulin, selectin, and proteoglycan (for example, syndecans) superfamilies. At the extracellular surface, the cell adhesion receptors recognize and interact with either other cell adhesion receptors on neighboring cells or with proteins of the ECM. ECM proteins are typically large glycoproteins, including the collagens, fibronectins, laminins, and proteoglycans that assemble into fibrils or other complex macromolecular arrays. Owing to their binding to adhesion receptors, they can also be tightly associated with the cell surface. At the intracellular surface of the plasma membrane, cell adhesion receptors associate with cytoplasmic plaque or peripheral membrane proteins. Cytoplasmic plaque proteins serve to link the adhesion systems to the cytoskeleton, to regulate the functions of the adhesion molecules, and to transmit signals initiated at the cell surface by the adhesion receptors. Several substrates different for the shape and physico-chemical properties are used for cell adhesion in artificial devices. Natural substrates such as ECM proteins (collagen, fibronectin, vitronectin, laminin) or polymers (chitosan, polylactic acid, polylysine, etc.) and synthetic substrates such as polystyrene, polycarbonate in the shape of scaffolds, gels, sponge, and membranes can be used in devices. Semipermeable membranes made from polyethersulfone, polysulfone, polycarbonate, polytetrafluoroethylene, modified polyetheretherketone, chitosan, polycaprolactone, polylactic acid, polyglycolic acid, and copolymers in flat and hollow fiber configurations are used for adhesion of different type of anchorage-dependent cells (hepatocytes, endothelial cells, neuronal cells, keratinocytes, progenitor cells, osteoblasts). In the case of bioartificial organs,

isolated cells are compartmentalized in a polymeric membrane which provides a number of important functions for the success of these devices. Membranes should act as barriers to immunocompetent species present in the patient's blood and should permit the rapid passage of key metabolites such as nutrients and oxygen from the surrounding to the cell compartment (Curcio et al. 2005). In such devices cells are contacting with membranes, the surface properties of membrane could affect the various bioresponses. Thus, one major approach of the materials scientists has been to try to influence the extent and the character of the cell response by modifying the surface composition and properties of the polymer. The response of cells to different material properties is a complex process and even minute changes in composition of the substrate produce amplified differences in cell responses. Although surface properties are often derived from the bulk properties of the materials, the bulk materials do not entirely define them, because the used substrates are coated with proteins almost immediately after implantation in the body or immersion in culture media. Surface chemistry and topography determine the identity, quantity, and conformational change of these adsorbed proteins. In particular, the roughness and pore size of polymeric membranes seem to play an important role since they have been shown to influence the viability and metabolic rates of cells (De Bartolo et al. 2008). Modification of surface chemistry including grafting of functional groups, peptides, and proteins represents a strategy to control cell responses in *in vitro* and *in vivo* systems. The most common peptide immobilized onto surfaces is RGD amino acid (arginine-glycine-aspartic acid) sequence that stimulates cell adhesion and growth since this peptide represents the minimal adhesion domains of the most ECM proteins (De Bartolo et al. 2005). The immobilization of specific moieties that interact with specific receptors of cell membrane is a challenge to enhance the selectivity of the membrane with respect to a cell type in order to employ it in tissue engineering for the reconstruction of a specific tissue. For example the immobilization of galactose motifs on the surface could enhance the specific interaction

with hepatocytes owing to the specific binding between the galactose moiety and the asialoglycoprotein receptor present on hepatocyte cytoplasmatic membrane (De Bartolo et al. 2006).

- S. Ringer demonstrated that a beating animal heart can be maintained in salt solutions. First attempts of cell cultures are dated 1885, when W. Roux observed for a week embryonic chick cells using only a saline solution as medium. Therefore, it is in 1907 that the father of the cell culture technique R. Granville Harrison published experimental results on the growth of frog nerve fibers in a lymph clot held by the hanging drop method. Benefiting from the strict aseptic culture conditions introduced by A. Carrel, the nobel prize for medicine and physiology in 1992, this experimentation carried out for several weeks, led the way to the development of an enormous variety of cell culture techniques and to the progresses of the sterile conditions and the employ of culture media more and more completed and balanced in composition (Karp 2010). *Cell culture setup*. The specific requirements for a cell culture depend mainly on the final application the work is fated; therefore, there are some specific instruments and parameters that must be used and observed. To the basic equipment made of cell culture hood, incubator, water bath, centrifuge, refrigerator and freezer, cell counter, microscopes, liquid nitrogen, cryostorage container, and sterilizer, other additional supplies are requested, as vessels, reagents, media, pipettes, and so on. Moreover, either the working areas or the operators must ensure the aseptic conditions essential for avoiding biological and chemical contaminations. Contaminants like bacteria, yeasts, molds, viruses, and mycoplasma are not easy to eradicate and may waste the experimentations (Alberts et al. 2002).

Cell Culture

Antonietta Messina and Loredana De Bartolo
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

“Cell culture” refers to a homogeneous group of cells able to grow and proliferate in controlled artificial environments for many generations. Generally derived from animal and plant, these eukaryotic cells are maintained in sterile vessels where a culture medium reproduces the nutritional and chemical-physical conditions of the native environment.

Some historiographical notes. The cell culture technique is only relatively a new science. Though the 1950s are considered the “cell culture years,” actually, already in the nineteenth century,

In a living organism, the cells survive due to the vascular system that brings the nutrients and removes waste product derived from the metabolism. In vitro, this function is entrusted to the culture medium. Classified in balanced salt solutions (PBS, Hanks' BSS, DPBS), basic media (MEM, DMEM), completed media (RPMI 1640, Iscove's DMEM, Leibovitz's L-15), and serum-free media (HAM F10, HAM F12), this specific isotonic solution is constituted by elementary substances and nutrients, as glucose, salts, amino acids, growth factors, carbohydrates, vitamins, lipids, and proteins, and a supplement of antibiotics is also requested for the inhibition of the

bacterial growth (penicillin 10,000 ug/ml; streptomycin 10,000 U/ml). A vitally important supplement of the medium is also the animal serum (FBS, NCS, HF). The serum, used in concentration of 5–20 %, is the main source of growth and adhesion factors (PDGF, EGF, IGF), hormones, lipids, and energetic sources. Moreover, it regulates cell membrane permeability and protects the cells from mechanical and chemical stresses, and its buffer power balances the pH value at 7–7.7. All the cell types need proper culture medium and supplements that must be refreshed regularly in aseptic condition to guarantee their survival (Alberts et al. 2002; Karp 2010).

Culture conditions. In artificial systems, the cell is traditionally cultured in plastic or glass vessels purposely made with different shapes and properties (flasks, Petri dishes, bottles). They are put in incubators where a temperature of 37 °C and a controlled atmosphere (95 % air – 5 % CO²) are set in order to mimic the native environment. In the field of tissue engineering and bioartificial organs, isolated cells are cultured on several types of biomaterials including polymeric and composite membranes, extracellular matrix components, and batch and dynamic systems. Depending on the cell types, there are two basic systems for growing cells in culture: the adherent culture system and the suspension system. The adherent culture system has been specifically developed for the growth of anchorage-dependent cells that derive from solid tissues and require to adhere to a substrate in order to survive and proliferate. On the basis of their morphology (shape and appearance) or on their functional characteristics, these cells are divided into two different typologies: the epithelial-like cells that appear flattened and polygonal in shape and the fibroblast-like cells, elongated and bipolar. The suspension culture, on the contrary, refers to the culture of anchorage-independent cells, as the blood or lymphatic cells that survive floating in suspension and assuming a spherical shape defined lymphoblast-like (Alberts et al. 2002; Karp 2010).

Isolation of cells. In order to set up a culture, the early stage is to acquire an already established cell line or strain or to isolate the desired cells

from a tissue fragment. When cells are immediately placed in a suitable culture environment after mechanical removal from a tissue, the so-called primary cultures are defined. To degrade the extracellular matrix responsible of the cell layer unity and to obtain a cell suspension, the tissue is enzymatically treated (collagenase, trypsin, protease), and the highly heterogeneous cell population is cultured in specific media able to separate single cell types interacting with the cytoplasmatic molecules expressed onto the plasmatic membranes (antigens). Despite having a finite life span due to the phenomenon of senescence, these cells proliferate until they occupy all the substrate available, reaching the confluence. At this stage, in order to avoid the degeneration and their death, the cells are enzymatically removed (e.g., trypsin, papain, collagenase in combination with EDTA) and transferred into a fresh growth medium in a new vessel (Hayflick 1998; Karp 2010). This procedure is called subculturing (passaging or splitting) and transforms primary cultures in “cell lines” or subclones, where the cells with the highest growth capacity predominate resulting in a degree of genotypic and phenotypic uniformity in the population. Moreover, when a subpopulation is further selected, this cell line becomes “cell strains” able to acquire additional genetic changes. The survival ability of normal cell cultures lasts only for a limited number of passages; however, some cells can become immortal due to a spontaneous or a viral-/chemical-induced modification. Acquiring the ability to proliferate indefinitely like the tumor cells, the characteristics of these transformed “continuous cell lines” are (i) the fast growth, (ii) the ability to grow up to higher cell density, (iii) reduced serum and anchorage dependence that allow the culture in suspension more than in adherent vessels, (iv) different in phenotypes from native tissue, and (v) stop expressing tissue-specific genes (Hayflick 1998; Alberts et al. 2002; Karp 2010). In order to preserve cell characteristic from further transformation or contaminations and to ensure the reproducibility of experimentation in time, a surplus of cells, derived from subculturing, can be treated with a cryoprotective agent (DMSO or glycerol) and stored at a temperature below 130 °C in liquid

nitrogen directly in the laboratories. Working stocks of cell lines are reposted in many cryopreservation banks including the American Type Culture Collection (ATCC) and the European Collection of Cell Cultures (ECACC) (Alberts et al. 2002).

The cell culture technology opens up new perspectives in many fields, as the manufacturing of vaccines and other products of biotechnology, and above all they became the turning point for the development of the tissue engineering, science entrusted of the study and production of artificial tissues and the regeneration of tissue and organs, either in 2D or 3D systems. Nowadays, the cell cultures are the “model system” and the perfect instrument for many applications: (i) production of pharmacological substances (antibodies, vaccines, growth factors, etc.), (ii) toxicity testing of drug effects, (iii) study of basic cell physiology, (iv) cancer research, (v) genetic engineering, (vi) tissue engineering and regenerative medicine, and (vii) gene therapy.

Cell Encapsulation

Cecile Legallais
UMR CNRS 7338 Biomechanics and
Bioengineering, Université de Technologie de
Compiègne (UTC), Compiègne, France

Encapsulation can be generally defined as a process that allows the entrapment of substances in a spherical-shaped porous material Chang (1964).

When sieving is ensured by an ultrathin membrane formed around a liquid core, the term of “capsule” is appropriate. When sieving is ensured by the whole core of the sphere, the term of “bead” is preferred and the porosity is homogenous across the structure.

In case of cell encapsulation for 3D tissue engineering, the goal is to host cells of a specific organ type into a porous scaffold in order to maintain their original functions and recreate a tridimensional organization mimicking the tissue to be replaced. Although many applications (such as pancreas, liver) have been developed in the last 30 years, there is still no clear consensus on the best choice for biomaterials and cells, whatever the organ type.

The materials hosting the cells should offer biocompatibility, adapted surface properties, and adequate porosity to allow the transfer of nutrients, oxygen, metabolites, and low molecular weight proteins such as albumin, but also immune protection and mechanical stability. They can be native or benefit from chemical and biological modifications to better mimic the cells’ niche and create micro-environments to control their response. Alginate is up to now the materials of reference. Alginate beads or capsules hosting cells are easy to produce by extrusion techniques, using coaxial air flow, electrostatic force, or vibrating nozzle to adjust the bead diameter. Encapsulation can be performed at room or body temperature, at physiological pH, and in isotonic solutions. The alginate bead or capsule might be coated in some approaches with a poly-L-lysine layer (PLL) to improve mechanical stability and reduce external porosity Orive et al. (2006). Other materials such as collagen, chitosan, gelatin, and agarose can also be employed, alone or in combination with alginate.

The spherical shape of beads or capsules provides them with interesting characteristics that can be considered advantageous to other porous scaffolds with plate or cylindrical (hollow fiber, for instance) geometries. This spherical shape is considered as the most efficient one for the promotion of mass transfer. Indeed, the sphere brings the best surface-to-volume ratio, leading to proper solutes’ bidirectional diffusion, provided that the sieving

Cell Encapsulation, Fig. 1 Principle of biohybrid constructs. (a) Description of the mass transfer expected between cell compartment and host. (b) Application to microencapsulation

properties of the material are tuned. The size of the beads or capsules related can be adjusted by the manufacturing process. Usually, their diameter does not exceed 500–1000 μm to avoid cell necrosis in the center. In addition, beads or capsules of this size can be easily frozen. Microencapsulation decreases cell damage during cryopreservation and allows thus an easy storage before use, leading to readily available encapsulated cells when needed.

The choice of cells depends on the targeted application as organ supply. For clinical application of tissue engineering, only primary cells (from animal or human origin) and cell lines have been employed. To reconstitute the functions of a failing organ or tissue, multiple pre-differentiated stem cell populations could be used and/or combined in biomaterials to form biohybrid constructs (Fig. 1).

Cell Membrane

► Cellular Membranes

Cell Recycle Membrane Fermentor

Lidietta Giorno

Institute on Membrane Technology, National Research Council, ITM-CNR, Rende, Italy

Synonyms

“Cell-Recycle Membrane (Bio)Reactor” (CRMR); Continuous Membrane Fermentor (CMF)

A cell-recycle membrane fermentor is a hybrid setup of traditional fermentor combined with a membrane filtration process (Fig. 1). In literature they are also referred to as “Cell-Recycle Membrane (Bio)Reactor” (CRMR); continuous membrane fermentor (CMF); etc. All of them have the same basic concept of catalytic membrane reactors, which combine the chemical conversion (in the specific case a fermentation) with the separation of the product by membrane operations.

The system consists of a fermentor connected to a membrane separation unit. The system as a whole can be seen as a catalytic membrane reactor in which the biocatalyst is compartmentalized in the bulk reaction by the membrane module. Cells, macromolecules, and solids are retained by the membrane and recirculated to the fermentor. Product and other small molecules permeate through

Cell Recycle Membrane Fermentor, Fig. 1 Schematic of a cell-recycle membrane fermentor (or continuous membrane fermentor) (Drioli and Giorno, 1999)

the membrane and are removed from the fermentor. The volume of fermentor is kept constant by adding fresh feed at the same rate as the permeate flow rate. The product is diluted in the fermentor solution; concentration is reduced and product inhibition is avoided or at least limited. Since the substrate (glucose, sucrose) and low molecular weight nutrients permeate through the membrane together with the product, it is convenient to start the ultrafiltration process when the concentration of nutrients is decreased and that of product is increased. It must be taken into account that the concentration of substrate should not be lower than the limiting value for the survival of cells.

Since in a continuous fermentation mode, the microorganism is continuously fed to the reactor, its density is increased considerably. This fact allows the reactor to operate at high biocatalyst concentration. On the other hand, an optimal cell density must be maintained in the fermentor by using an appropriate bleed rate. In fact, high dense and viscous solutions are difficult to be treated by membrane processes. Furthermore, the fouling created by the macromolecules decreases membrane separation efficiency. This means that part of the fermentation broth has to be removed and

replaced with fresh medium at regular intervals of time to maintain good process performance.

The process variables in a continuous membrane fermentor are

- Flow rate of fermentation broth Q (l/h)
- Dilution rate, $D = Q_p/V$ (h^{-1}); where Q_p = permeate flow rate; V = fermentation volume
- Bleed rate, B (h^{-1})
- Starting time of ultrafiltration after onset of fermentation

These parameters have to be optimized case by case. In general, production rate is related to the dilution rate, in particular the production rate increases with increasing dilution rate. The productivity of continuous fermentation is higher compared to batch fermentation. However, final product concentration in the permeate is lower than the case of batch fermentation.

The economic advantage of high productivity process decreases rapidly when product concentration decreases. Lactic acid production by continuous membrane fermentor is interesting on an economic basis when production is on a relatively small scale and the lactic acid concentration is as

high as possible. The main reason for this is the high cost for water removal.

It is expected that the performance of the continuous membrane fermentor can be improved by integrating it in a continuous downstream process which selectively separates the lactic acid and recycles the substrate and nutrients, permeated through the UF membrane, back to the fermentor solution. For the downstream processing, electro-dialysis, membrane-based solvent extraction, and nanofiltration are among the most suitable methods.

When kinetic models for the growth and fermentation of a specific kind of cell or microbe on the corresponding substrate medium are available, mathematical modeling of membrane fermentors can be accomplished according to mass balances and the kinetics.

A steady-state mass balance on a continuous cell recycle fermentor over the vessel alone is as follows:

$$a' FX - (1 + a') FX + V\mu^* X = 0 \quad (1)$$

on cells, and

$$X' = Y D(S_f - S)/\mu^* \quad (2)$$

on limiting growth substrate to give a cell concentration value in the vessel equal to

$$X' = Y(S_f - S)/(1 + a' - Ca') \quad (3)$$

where

a' = recycle ratio

F = feed flow rate, $L^3 T^{-1}$

S_f = feed substrate concentration, ML^{-3}

S = substrate concentration, ML^{-3}

X' = cell concentration, ML^{-3}

X'_1 = cell concentration entering the membrane module, ML^{-3}

X'_2 = cell concentration in the recycle stream, ML^{-3}

μ^* = specific cell growth rate, T^{-1}

Y = organism yield coefficient, i.e., mass of cells formed/mass of nutrients

C = concentration factor

The specific growth rate (SGR) can be expressed as a linear function of the specific substrate utilization rate, KS , to give

$$SGR = Y.KS - D \quad (4)$$

where

KS = the specific substrate utilization rate, mass/mass time

D = the organism decay coefficient, $1/\text{time}$.

The kinetics of substrate removal in an anaerobic reactor actually determines the solid retention time (SRT) required for a given fermentation efficiency. In turn, the presence of the UF unit allows a fine control of SRT, making process control easier. When high biomass concentrations are achieved, longer SRTs can be maintained at lower reactor volumes.

The volumetric loading to a reactor, VL , is defined as

$$VL = Q Sf/V = Sf/t \quad (5)$$

where

V = reaction volume, L^3

Q = flow rate, $L^3 T^{-1}$

High biomass concentrations permit operation at higher volumetric loading rates. Reactor design can be carried out by estimating the value of volumetric loading necessary to achieve a given effluent quality. This design criterion is commonly used for biological systems where the evaluation of biomass concentration within the reactor is difficult. This is not the case with cell recycle fermentors, so the VL or the SRT approach can also be used as design criterion.

In continuous membrane fermentors productivity is a function of viable cell concentration within the fermentor. Cell recycle allows to operate at higher microbial cell concentrations than in conventional batch fermentors, reducing the volume required for a given productivity and hence the capital costs. On the other hand, the viscosity of the cell slurry increases with cell concentration, and concentration polarization phenomena are usually significant.

Systems such as rotating membrane modules, backflushing operations, etc. can be used to overcome fouling and expected concentration polarization problems. Provided cell resistance to shear stress, concentration polarization is usually controlled by operating the reaction system at high recirculation rates.

When concentration polarization occurs, permeate fluxes become invariant with the transmembrane pressure, and increases in the permeation rate can be achieved only by appropriate fluid dynamics conditions. The design of the UF membrane unit in the polarized regime must relate the flux to the optimal level of reactor volatile suspended solids (VSS) or total suspended solids (TSS) according to Michaels' gel theory, to give

$$J = K_S \ln (C_g/C_b) \quad (6)$$

where

K_S = the overall mass transfer coefficient, LT^{-1}

C_g = apparent solid concentration in the gel, ML^{-3}

C_b = concentration in the bulk, in the specific case, concentration of VSS or TSS, ML^{-3}

High recirculation and dilution rates help in maintaining low levels of inhibitory products.

Cell Separation

Loredana De Bartolo

Institute on Membrane Technology, National Research Council, ITM-CNR, Rende, Italy

Cell separation is the process aimed at separating cells. Cells can be separated on the basis of different size, shape, physicochemical characteristics, specific molecules, or receptors present over their plasmatic membrane (Orfao and Ruiz-Arguelles 1996).

Traditionally cells are separated through centrifugation technique for the different density and size. This technique only requires the resuspension of the cells in an appropriate buffer and the knowledge of their approximate composition and density or size. Cells of different masses and densities are pelleted accordingly, with the densest cells pelleting first and at comparatively low centrifugation speeds, while the smallest, lightest cells require much faster speeds. The pellets can then be collected and resuspended in the desired buffer. Another method consists to use antibody which are able to recognize cell membrane proteins. All cells have an array of proteins on their surface membrane, some of which are found only on particular cells. The antibodies are often tagged with a fluorescent compound (fluorophore) so that the whole cell suspension can then undergo flow cytometry, which will identify and then isolate each cell individually. The antibodies can be also combined with a tiny magnet. The cells are then applied to a magnetic column that is capable of retaining these tagged cells when a magnetic field is generated within it. Cells can be separated through a biochemical method, which involves perturbing a biochemical process that is required by the cell for its growth and/or survival, and it should only be performed if a drastic manipulation will not detrimentally affect other steps in the experiment. Biochemical separations include blocking DNA synthesis, e.g., with hydroxyurea, and serum deprivation, i.e., growing cells in serum-free media for a specific amount of time. Membrane processes are used for separation of blood cells from other blood components through filtration. Cells are isolated by using membranes with suitable molecular weight cutoff that permit the passage of all components excluding only cells. Membrane filtration has also been used for the industrial separation of blood cells. Blood for transplantation is typically passed through membrane filters to eliminate leukocytes, which can help prevent infection by viruses such as human immunodeficiency virus and hepatitis C virus. Compared with other cell separation methods, membrane filtration is simple and inexpensive, and it is easy to maintain sterility during the process. Various porous polymeric membranes have been used for separation by filtration of different types of marrow

stromal cells (KUSA-A1 osteoblasts and H-1/A preadipocytes), due to the different cell size (Higuchi et al. 2005). Separation of hepatocytes and fibroblasts has been realized through surface-modified polyurethane membranes combining the filtration process with the use of negatively charged membranes (Higuchi and Tsukamoto 2004).

Cellophane

M. S. Mohy Eldin
Polymer Materials Research Department,
Advanced Technologies and New Materials
Research Institute (ATNMRI), City for Scientific
Research and Technology Applications (CSRTA),
New Borg El-Arab City, Alexandria, Egypt

Cellophane is made from regenerated cellulose in the form of thin and transparent films. The name of

Cellophane was derived from the French words cellulose and diaphane (transparent). Cellophane was invented by Swiss chemist Jacques E. Brandenberger while employed by *Blanchisserie et Teinturerie de Thaon* (Wikipedia free encyclopedia). In 1900, he started his first try. After almost 10 years, 1910, Brandenberger improves his film by adding glycerin to soften the material. By 1912 he had constructed a machine to manufacture the film and cellophane was patented that year (Carlisle 2004).

Cellophane manufacture process includes many steps. The first step is to dissolve cellulose in alkali and carbon disulfide to have a “viscose” solution. The second step is the extrusion of the viscose solution through a slit into a bath of dilute sulfuric acid and sodium sulfate to reconvert the viscose into cellulose film. The third step is the passing of the film through several more baths, one to remove sulfur, one to bleach the film, and one to add glycerin to prevent the film from becoming brittle.

The properties of cellulose membrane are intimately related to their structure and morphology which are mainly controlled by conditions, nature, and mechanism of coagulation. Therefore, to design desired morphology and properties, the cellulose membrane coagulated in different coagulation baths such as water and sulfuric acid aqueous solution (Fink et al. 2001; Hongo et al. 1999; Inamoto 1996; Manabe 1987; Abe and Mochizuki 2002; Bang 1999; Rosenau 2001). Owing to its high production costs and environmental pollution problems, it has great significance to develop simple producing process for cellulose membrane using new and powerful organic solvent *N*-methylmorpholine *N*-oxide (NMMO) to dissolve cellulose straightaway without any complex formation (Fink et al. 2001). The obtained cellulose membranes exhibited excellent mechanical properties and permeation characteristics (Fink et al. 2001; Abe and Mochizuki 2002; Bang 1999; Rosenau 2001).

Applications such as packaging for a variety of food items, base for such self-adhesive tapes, battery, and dialysis tubing (Visking tubing) and as a release agent in the manufacture of fiber glass and rubber products have been recognized.

Cellophane Membranes

M. S. Mohy Eldin

Polymer Materials Research Department,
Advanced Technologies and New Materials
Research Institute (ATNMRI), City for Scientific
Research and Technology Applications (CSRTA),
New Borg El-Arab City, Alexandria, Egypt

Cellophane membranes are regenerated transparent cellulose membranes of high hydrophilicity, good mechanical properties, and biodegradability, biocompatibility, and gas barrier characters. The crystallinity and porosity of the membranes have been controlled through the regeneration conditions over the last decades. Recently, these characters are under control after investigating and using new

types of solvents for cellulosic materials especially ionic liquid solution. According to these characters, different applications of cellophane membranes have been recognized such as food packaging which represents the oldest one (Stocking and Mueller 1955). Hemodialysis cellophane membranes are one of the first applications in dialysis biological fluid (blood) to eliminate unwanted substances such as urea and creatinine. The cellophane membranes were used in planer form to dialyzed blood against electrolyte solution in artificial kidney (Mollison and Graydon 1977). Separation between two electrolytes as ionic barriers (battery separator) is one of the most known industrial applications of cellophane membranes. As a separator, it has “achieved the following objectives: (1) immobilization of the electrolyte by absorption in the cellulose, (2) elimination of the gases evolved in the operation of the cell, (3) prevention of mutual penetration of the active materials, and (4) homogeneous and reversible deposition of the negative active material (Zn) from the electrolyte (Claudia and Evans 1964)”. As ionic conductors, ion exchange cellophane membranes have been developed as fuel cell ion exchange membranes (Abu-Saied et al. 2012, 2013). The cellophane membranes act to conduct hydrogen ions and separate fuel from crossover to the anode compartment in the polyelectrolyte fuel cells. Due to cellophane membrane hydrophilicity, low nonspecific adsorption (Zou et al. 2001; Crawford et al. 1999), and good chemical stability, they were adapted as base for affinity separation chromatography membranes for proteins. Mohy Eldin et al. 2009 developed immobilized metal ion affinity membranes from poly(glycidyl methacrylate) grafted cellophane membranes for separation of β -galactosidase enzyme. Later on Mohy Eldin et al. 2011 developed immobilized metal ion affinity membranes from poly(methacrylic acid) grafted cellophane membranes for separation of His-Tag chitinase.

Synonyms

Biological membrane; Biomembrane; Cell membrane; Plasma membrane

Cellular membrane (or biomembrane) is the biological membrane that surrounds and protects the cell and governs the transport of matter, energy, and information between the external and internal (and vice versa) of the cell.

Living cells are divided into several compartments and sub-compartments by a membrane. Each compartment has a specific function and structure and the interactions between compartments are highly regulated by specific signals. The corresponding delimited spaces or compartments are called organelles; in eukaryotic cells the main are endoplasmic reticulum, Golgi apparatus, nucleus, mitochondria, lysosomes, endosomes, and peroxisomes. Each membrane-enclosed organelle contains a specific set of proteins free or on the membrane surface that regulate many vital biochemical processes.

Cellular membrane is a complex system with multifunctional properties, acting as a separating/contacting barrier within or around cell and cell components. This system controls the selective transport of components and regulates the passage through the different compartments. In addition biological membranes have mechanical and elastic properties given by the interaction with intracellular skeleton and, if present, the extracellular cell wall (such as fungi, etc.).

In general, the biological membrane is formed by a continuous, water-impermeable, double layer of phospholipids containing a myriad of macromolecules and their complexes through which transport is promoted. According to the fluid mosaic model, the cell membrane is a two-dimensional fluid of proteins and lipids (Singer and Nicolson 1972).

The biological membrane is a dynamic and fluid structure, which implies that the molecules have a substantial degree of mobility in the two-dimensional membrane plane. This allows rapid lateral diffusion of lipids and proteins within the planar membrane surface. In contrast to lateral movement, the transbilayer or “flip-flop” diffusion of lipids from one leaflet in the bilayer to the other occurs very slowly. Transbilayer movement requires that a polar or charged head group leave its aqueous environment and move into the hydrophobic interior of the bilayer.

The fluidity of a membrane depends on its composition, the temperature, and how the different components are packed and organized in the membrane. In general, membrane fluidity is

decreased by lipids with long or saturated fatty acid chains, whereas lipids with short or unsaturated fatty acid chains tend to increase the fluidity of a membrane (Bittar and Bittar 1997). There are three major types of lipids found in the biological membrane: phospholipids, cholesterol, and glycolipids. Phospholipids form a bilayer in which the nonpolar regions of the lipid molecules in each layer face the core of the bilayer and their polar head groups face outward, interacting with the aqueous phase on either side.

Cholesterol is another important component found in the eukaryotic cell membranes. It has a rigid structure that stabilizes the membrane and reduces the natural mobility of the complex lipids in the plane of the membrane. Increasing amounts of cholesterol make it more difficult for lipids and proteins to move in the membrane.

Proteins are the second major component of the cell membrane, present in about equal proportion by weight with the lipids. Proteins are embedded in this bilayer sheet, held by hydrophobic interactions between the membrane lipids and hydrophobic domains in the proteins.

Membrane proteins can be classified according to their relationship with the lipid bilayer into two types: peripheral proteins (or extrinsic proteins) that are outside of the lipid bilayer without completely crossing the membrane and integral proteins (or intrinsic proteins) that cross the lipid bilayer only once or many times.

The proteins embedded in the cell membrane play a variety of roles. Many peripheral membrane proteins are enzymes, and many membrane-spanning integral proteins are carriers or channels (aquaporins) for the movement of water-soluble molecules and ions into and out of the cell. Another important role of membrane proteins is structural; for example, certain membrane proteins in the erythrocyte help maintain the biconcave shape of the cell. Finally, some membrane proteins serve as highly specific receptors on the outside of the cell membrane to extracellular molecules, such as hormones. The selective and regulated passage of molecules and ions across the cell membrane is an essential

component of cellular homeostasis. The selective passage of solutes across the cell membrane, a physiological property known as membrane permeability, is mediated by the presence of membrane transport proteins that span the phospholipid bilayer. Transport mechanisms may be distinguished thermodynamically according to their ability to mediate active or passive transport. The active transport is defined as movement of a solute across membranes from areas of low concentration to areas of high concentration. This process is done by carrier proteins and uses energy to transfer solutes against their concentration gradient. The most common source is the hydrolysis of ATP (adenosine triphosphate). Others include light energy and the energy stored in ion gradient. In addition, exocytosis and endocytosis are other transport mechanisms used for the movement of large molecules across the membrane. During exocytosis the macromolecules are contained within vesicles which fuse with the cell membrane to release their contents to the outside. In endocytosis the reverse takes place: the substances to be taken in by the cell are gradually enclosed by a region of cell membrane until a vesicle containing the substances is formed. Regarding the passive transport, it is defined as movement of a solute from a region of high concentration on one side of the cell membrane to a region of lower concentration on the opposite side (no energy is required to move a substance). The speed of solute diffusion depends on the difference of concentration, the size of the molecules, and the possible interactions of the diffusible substance with water. The diffusion across the membrane can be described by Fick's law:

$$J = -DA \frac{\Delta c}{\Delta x}$$

where J is the rate of diffusion, D is the diffusion coefficient, A is the membrane area, Δc is the concentration difference across the membrane, and Δx is the thickness of membrane.

The principal driving force for the passive diffusion of an uncharged solute across the plasma

membrane is the difference of concentration between the inside and the outside of the cell. In the case of an electrically charged solute, such as an ion, diffusion is also driven by the membrane potential, which is the electrical gradient across the membrane (Considine 2013). The cell employs three main mechanisms to carry out the passive transport:

- Simple diffusion is the passage of lipid-soluble solutes across the plasma membrane.
- Osmosis: in this process, the spontaneous movement of water across a membrane driven by a gradient of water concentration and the movement of water from a solution of high water concentration (low concentration of solute) toward a solution with a lower concentration of water (high solute concentration). Osmosis is a passive transport mechanism that tends to equalize the total solute concentrations.
- Facilitated diffusion is the movement of water-soluble solutes and ions through a channel or across the transmembrane transporter.

In addition to lipid and proteins, in the cell membrane, there are carbohydrates, which are attached to the proteins forming glycoproteins, or to some of the lipid classes, forming the glycosphingolipids. Protein-bound carbohydrate residues are on the extracellular surface of the cell membrane and take part in cell-cell interactions, including those of the immune system (Stein and Litman 2015).

Cellulase in Membrane Bioreactors

Katalin Belafi-Bako

Research Institute of Bioengineering, Membrane Technology and Energetics, University of Pannonia, Veszprem, Hungary

Membrane reactors have been developed mainly for catalytic reactions, using various membrane modules (e.g., flat sheet, hollow fibers). If biocatalysts (enzymes or cells) are applied, the equipments can be operated as membrane *bioreactors* (Drioli and Giorno 1999). One of the main advantages of the membrane bioreactors is that they make recovery and reuse of biocatalysts possible.

Usage of membrane bioreactors is especially beneficial for polymer degradation processes, where the small size product may have inhibitory effect, but can be separated easily by a proper porous membrane. This is the case of enzymatic hydrolysis of polysaccharides, like cellulose or starch. The long polysaccharide chain as well as the biocatalyst (enzyme or cell) are rejected by the membrane, while the product (glucose) passes through the membrane into the other phase. In such a system, continuous uptake of substrate and release of product without loss of biocatalysts can be achieved.

The huge amount of biomass produced annually worldwide is mainly composed of cellulose; its application for various purposes (industrial raw material, bioethanol, etc.) is extremely important nowadays. In these cases cellulose should be degraded by hydrolysis, resulting in glucose (monomer of cellulose). Enzymatic cellulose hydrolysis is carried out by various cellulases.

In general, hydrolysis of cellulose is more difficult to achieve than that of the other polysaccharides. The process is influenced by three main factors: the nature of the enzymes; the structure of the substrate; and the enzyme-substrate interactions (Mansfield et al. 1999). The action of the *cellulase enzyme system* includes three main

groups: endoglucanases, cellobiohydrolases, and cellobiases (β -glucosidase). These enzymes work in a synergistic mode to degrade cellulose, therefore it would be more effective to apply the whole complex enzyme system. One of the most effective cellulase systems can be obtained from the fungus *Trichoderma reesei*.

The main difficulty in cellulose hydrolysis is attributed to the *dual nature of the substrate*. The accessibility of the crystalline and amorphous regions is different; moreover, the solubility of the substrate is limited.

Finally in the *enzyme-substrate interactions*, it should be considered that hydrolysis of cellulose is a surface phenomenon. Before the reaction itself, the enzyme has to be bound to the substrate, i.e., the process requires the adsorption of the biocatalyst onto the insoluble substrate prior to the hydrolysis.

In a recent work, a membrane bioreactor was used with a hairy membrane layer (Bélafi-Bakó et al. 2006) that offered a special surface area for simultaneous adsorption of the substrate and enzyme. In this way the cellulose-cellulase layer formed provided a further advantage: diffusion resistance between the substrate and enzyme was reduced. Since solid particles present might cause troubles (fouling), it required special conditions for the construction of the membrane reactor. To avoid blockage, tubular type membrane module was used in the experiments. The simultaneous, reversible immobilization of the biocatalyst and the substrate onto the membrane surface was found to improve the efficiency of the process.

Cellulose Derivatives

Hongyang Ma, Benjamin S. Hsiao and Benjamin Chu

Department of Chemistry, Stony Brook University, Stony Brook, NY, USA

Cellulose derivatives used in membrane fabrication are mainly referred to cellulose esters, in which cellulose acetate, cellulose diacetate, cellulose triacetate, and cellulose nitrite are typical components. There are other cellulose esters, including cellulose acetate propionate, butyrate, octanoate, benzoate, methyl carbonate, and methoxyacetate, which have also been used to fabricate membranes, with/without combination of cellulose acetate (Fig. 1). Membranes fabricated from single or multiple cellulose derivatives can be used in all fields of water purification, gas separation, and biomedical applications, where the morphology (e.g., pore size) and structure of the membrane can be flexibly adjusted through different preparation pathways (Ulbricht 2006).

Another widely used cellulose derivative is cellulose ether (e.g., ethyl cellulose), which has been demonstrated in fabrication of membranes for gas separations, such as hydrogen, oxygen, nitrogen, carbon dioxide, and methane (Mulder 1996).

Membranes fabricated from cellulose derivatives for separation applications offer several advantages: (1) a variety of cellulose derivatives with different physical and chemical properties are available; (2) good chemical resistance and mechanical properties are attainable; (3) cellulose derivatives are cost-effective; and (4) readily available surface functionalization pathway can offer new opportunities to generate new functional membranes. For example, the nanofibrous membrane fabrication approach (e.g., electrospinning to produce nanofibers) using cellulose derivatives, in combination with surface grafting of functional molecules and/or inclusion of nanoscale additives to create a nanocomposite structure, has expanded the family of cellulose membranes and opened many new separation applications (Ma et al. 2012).

Central Nervous System in Relation to Membranes

Loredana De Bartolo and Antonietta Messina
Institute on Membrane Technology, National
Research Council, ITM-CNR, Rende, Italy

The central nervous system (CNS) is the most complex organ in the human body. It consists of two components, the brain and the spinal cord.

The spinal cord attends the communication pathway between the brain and the periphery, and like the brain, it is made of a gray matter, constituted by the bodies of the neurons, and a white matter, constituted by their myelinated axons, serving the impulse transmission. Moreover, a special blood-spinal cord barrier made of endothelial cells and astrocytes protects the spinal cord from the biological and chemical changes coming from the periphery. It was long believed that regenerative processes in the CNS were completely absent, then after an injury, the recovering of the axonal function was impossible (Kandel et al. 2000). In the early 1980s, therefore, it was discovered that CNS retinal neurons were able to regenerate in bioengineered devices of peripheral nerves, highlighting that the nearly absent ability to regenerate the central neurons does not lie in the cells themselves but in their surrounding environment. After physical trauma, hypoxic events, and degenerative pathologies, a rapid severing of the axons occurs, and in the spinal cord, cell death is recorded in high extent due to the lost electrolytic homeostasis and the accumulation of free

radicals and toxic factors that stimulate apoptotic events. While the peripheral nervous system (PNS) consists of a particular glial cell population able to proliferate and produce specific factors (BDNF, CNTF, GDNF) involved in the axonal regeneration across the area of injury, the oligodendrocytes constituting the main part of the central glia are not able to provide similar support after damage. In the injury site of the central nervous system, they secrete numerous inhibitor factors for the axonal regeneration, including NOGO proteins, NI-35, chondroitin sulfate proteoglycans (NG2), and keratan sulfate proteoglycans. The produced signaling factors that play neuroprotective and regenerative roles appear, then, to be not enough to oppose this inhibition and the inflammatory events occurring after the damage. Furthermore, astrocytes, another component of the central glia, became proliferative. In order to protect the severed site from external molecules and the spreading of apoptotic events, they form a tight network called a glial scar, which obstruct the axonal regeneration, creating a wall that axons and neurogenerative factors cannot overtake (Horner and Gage 2002). Thus, manipulation of the chemical and biological environment around the injured site represents the key of the treatment of the CNS damages. Specifically, in order to promote the axonal regeneration of the central neurons, the neurogenerative and neuroprotective factor levels should increase (Recknor and Mallapragada 2006). Nowadays, it is well known how neural cells respond to their microenvironment, enhancing adhesion, proliferation, and migration along the regenerating site. Smooth surfaces, patterned supports, and structures with high mass transport properties are the main characteristics allowing the neural regeneration both in vivo and in vitro systems (Morelli et al. 2012). Since decades ago, the gold standard of the nervous system injury treatment is the transplantation of nerve grafts able to substitute the malfunctioning or lost areas of the system. Despite the implantation of nerve grafts allowed to reach important results in the recovery of movement and sensibility of the PNS, the central nervous system is hard to be treated, particularly when inner regions of the brain are severed, then

new approaches appeared to be necessary for the treatment of the CNS injury. Due to the development of biomaterials and new processing methods for the scaffold design, tissue engineering and chemotherapeutic strategies are the main approaches for the development of regenerative strategies able to guide axonal outgrowth. A wide range of natural and synthetic biomaterials is available to prepare neural scaffolds and releasing devices (Tysseling and Kessler 2011). Different classes of biodegradable polymers are available, including polycaprolactone, polyurethanes, polylactic derived, polyglycolic acid, chitosan, agarose, polysaccharides, collagen and various ECM proteins derived. Due to their controlled bioerosion, these materials allow the design of different bioengineered devices, with different shapes and configuration purposely made for bridging the nerve growth or the factors' release. Any biomaterial used to prepare neural scaffolds possess, in addition to biocompatibility, an appropriate range of permeability, porosity, and biomechanical properties serving to avoid the compression of the regenerating nerves or the sudden collapse of the device in the treated site. Actually, three different strategies are available for the treatment of the CNS injury: the entubulation models, the drug delivery systems, and the cell therapy. All of them are categorized as membrane system devices due to their mass transport properties they allow the diffusion, release, and removal of the different factors involved after an injury.

The entubulation strategy consists in the transplantation of tubular scaffolds purposely made to mimic the peripheral nerve tissue. Considering that the PNS is characterized by a regenerative ability due to proliferation of glial cells and the secretion of neuroprotective and neuroregenerative factors, many devices have been developed with the aim of entrapping the central axons in a protect environment, where inhibitor factors are not allowed to pass through and neuroregenerative signals are enhanced. These bioartificial tubular nerve grafts are meant to ensure a correct diffusion of nutrients and oxygen and purposely designed with specific thickness, mechanical strength, dimension, and

porosity degree. Tubular nerve grafts made of PLLA, PCL and PGA, and collagen and chitosan already extensively used for peripheral nerve regeneration are nowadays applied for the treatment of CNS injury models, alone or in conjunction with brain-derived neurotrophic factor (BDNF) to promote the axonal regeneration (Recknor and Mallapragada 2006; Morelli et al. 2012). Cell-adhesive proteins such as collagen, laminin, and fibronectin, which bind strongly the integrin receptors on the cell surfaces, assist the nerve regeneration. They are often used to coat the lumen of the bioartificial channels or to modify the biomaterial used for the device preparation in order to enhance the cell response and the regenerative process. The patterning of polymeric tubular membranes with short oligopeptides derived from ECM proteins is another way to increase the neurite outgrowth and the cytoskeleton organization in the regenerating neural tissue. Along similar lines, the incorporation of hydrogels into the nerve tubes have been evaluated with encouraging results for CNS applications. Collagen, hyaluronic acid, agarose, alginate, chitosan, methyl cellulose, xyloglucan, matrigel, fibrin, polysia-based hydrogels, peptide hydrogels, as well as synthetic hydrogels, such as polyacrylamide and polyethylene glycol hydrogels, revealed to be the best alternative to the classical polymeric nerve guidance grafts. Bioengineered tubular scaffolds have been combined also with cells providing a promising new approach for the CNS injury treatment. Since 1998, it is well known that remyelination of central axons can be promoted by using Schwann and olfactory glial cells entubulated in bioartificial scaffolds, and moreover, Schwann cells, when seeded in combination with neurotrophic factors or hormones, facilitated the axon regeneration. Therefore, the strategy is to entubulate neural stem cells (NSC), which possess the ability to differentiate into neurons, astrocytes, or oligodendrocytes in presence of specific growth factors and appropriate chemical environment. Despite the risk of uncontrolled proliferation and some problems in the maintenance of cell viability, the use of the neural stem cells in membrane systems is still the most promising approach. *Drug*

delivery strategy. When a nerve guide or other bioartificial implants are not appropriate due to the impossibility to reach the severed central nervous area, the delivery system of neurogenerative and neuroprotective factors represent the alternative strategy. A few molecules of natural and synthetic origin showed to promote the neural regeneration. Steroids, minocycline, interleukin 10, erythropoietin, and neurotrophins, like NGF, BDNF, and CNTF, are just some of the neuroprotective agents implied in the inhibition of the inflammatory response, microglial activation, and apoptotic event after a central injury (Kandel et al. 2000). Induction of the regeneration-associated genes expression (RAGs) or the Rho-Rock pathway inhibition is some of the neurogenerative properties of the neurotrophins. Moreover, they promote their remyelination, the sprouting and growth of new neurons with functional recovery. Whether the factors possess neuroprotective or neurogenerative ability, the delivery strategies are the same. Growth factors, proteins, and drugs are encapsulated into the devices made of polymer, hydrogels, or proteins and injected in the spinal cord through epidural and intrathecal routes for the spinal cord regeneration. Hydrogels, liposomes, fibrin, collagen-based, and other polymeric delivery devices obtained from natural and synthetic biomaterials have been implanted subcutaneously near the spinal cord's injured site, allowing the continuous release of the neuroprotective and neurogenerative agents and the partial recovery of the axonal functionality (Zhong and Bellamkonda 2008). *Cell therapy.* The drug/biological delivery strategies are easy with respect to the entubulation methods, but in truth, they have one disadvantage: the constant drug dose is achievable only with reinjection of new delivery devices. The cell therapy, instead, relies on a longer production of the therapeutic factors through the cell stimulation in the injured site or the transplantation of autologous, allogenic, or xenogenic cells. Generally, the cell therapy is used for the treatment of the neurodegenerative pathologies and of the chronic pain. In order to implant the cells in the interested site, specific polymeric carriers are available.

A few trial models suggested that this kind of approach could enhance the chances of the patient to recover partially the neuronal functionality, opposing the symptoms and the cognitional problems. Polymeric membranes ensure a consistent advantage for that kind of application, which consists in the chance to control cell viability and the diffusion of nutrients and at the same time, the protection of the cellular population from the immunological reaction of the body. Genetically engineered cells encapsulated into hollow fiber membranes are able to produce and release ciliary neurotrophic factor (CNTF) in patients affected by amyotrophic lateral sclerosis. Parkinson's disease is another degenerative pathology treatable with the cell transplantation. In this case, dopamine-producing cells, dispersed also in different hollow fiber membranes of alginate, showed an increase of the recovery and an analgesic effect in the patient (Cho and Borgens 2012; Morelli et al. 2012). Therefore, the low percentage of cells surviving after implantation and the host rejection and the inflammatory response represent the main disadvantages of the cell therapy strategies. For this reason, despite the encouraging results available, the complexity of the central nervous system made the regenerative strategies always promising and not conclusive at the same time, and further investigation must be done in order to ensure a safe and functional approach for the recovery after an injury.

Ceramic Membrane for Pervaporation

Wanqin Jin

State Key Laboratory of Materials-Oriented Chemical Engineering, Nanjing University of Technology, Nanjing, China

Ceramic membrane for pervaporation, which is also called inorganic pervaporation membrane, belongs to inorganic microporous membranes made from silica, alumina, or zeolite, which has a narrow pore size distribution typically with pore diameter smaller than 1 nm. Inorganic pervaporation membranes have better structural stability without the problems of swelling or compaction relative to organic membranes. They usually can withstand harsh chemical environments and high temperatures (Wee et al. 2008). Most of the inorganic pervaporation membranes are asymmetrical, with several macroporous support layers providing the mechanical strength and a microporous selective top layer providing the selectivity. According to the membrane materials, inorganic pervaporation membranes generally have two kinds: zeolite membranes and silica membranes.

Zeolites are microporous aluminosilicate minerals with crystalline structures that have uniform and molecular-sized pores, which have been used extensively as catalysts and adsorbents. Zeolite membranes are synthesized by the deposition of continuous polycrystalline zeolite layers on porous supports, first reported by Suzuki in 1987 (Suzuki 1987). Zeolite structures are made up of TO_2 , where T represents tetrahedral framework atoms, such as Si, Al, B, Ge, Fe, and P. Most zeolites contain Si with other metals substituted

Ceramic Membrane for Pervaporation,

Fig. 1 Atomic stick representations for the frameworks of CHA (a), MFI (b), and MOR (c) zeolite structures. The nodes represent tetrahedral framework atoms and the sticks represent oxygen bridges (Reproduced from Bowen et al. 2004)

into the framework (Bowen et al. 2004). The zeolite pores are made from rings in the framework and are designated by the number of oxygen atoms making up the ring. Small-pore zeolites include those structures made up of eight-member oxygen rings, medium-pore zeolites have 10-member rings, and large-pore zeolites have 12-member rings. Examples of each of these are shown in the ball-and-stick representations of zeolite frameworks in Fig. 1 (Bowen et al. 2004). Several zeolite structures such as MFI, LTA, MOR, and FAU are widely reported as zeolite membranes used for pervaporation, due to their unique characteristic such as pore structure, adsorption properties, and their mechanical and chemical stability, as described in Table 1 (Baerlocher et al. 2002). Zeolite membranes are most often prepared by hydrothermal synthesis, including in situ synthesis, secondary growth method, continuous flow synthesis method, microwave synthesis, etc. (Wee et al. 2008). By utilizing the properties of molecular sieving and preferential adsorption, the current pervaporation applications of zeolite membranes mainly include alcohol (e.g., ethanol, isopropanol, butanol)

dehydration, organic/organic separations (e.g., xylene isomers, methanol/methyl-tert-butyl ether mixtures, methanol/benzene mixtures), and acid separations (e.g., acetic acid/water mixtures). In 2000, the first industrial-scale separation plant, based on NaA zeolite membrane for pervaporation dehydration of organic-water mixtures, was developed by Mitsui Engineering and Shipbuilding Co. Ltd. in Japan (Morigami et al. 2001). Until Now, NaA zeolite membranes have been commercialized by the Busan Nano-Research Institute Inc. (BNRI, a subsidiary of Mitsui), SMART Chemical company (UK), Inocermic GmbH (Germany), and Nanjing Jiusi Hi-Tech Co. (China) (Gascon et al. 2012). Unfortunately, NaA zeolite membranes are very sensitive to even the slightest acidity.

Another kind of ceramic membrane for pervaporation is silica membranes, which now are commercially available and developed by The Netherlands Energy Research Corporation (ECN) (Verkerk et al. 2001). The microporous silica membranes consist of four support layers of α - and γ -alumina, and the selective top layer at the outer wall of the tube is made of amorphous

silica. Silica membranes are mechanically and chemically robust. Not only are the silica membranes stable in a normal industrial environment, they can even be used to remove water from condensation reactions like esterifications, where strongly acidic conditions predominate. However, silica membranes are not stable against water, and thus the addition of oxides such as ZrO_2 and TiO_2 is often employed to improve the membrane stability toward water and alkali (Wee et al. 2008).

Ceramic Membranes

Bo Wang

Department of Chemical Engineering, Imperial College London, London, UK

Ceramic membranes are made of ceramic materials, and to be specific, they must undergo a high-temperature sintering process to fall into the “ceramic membranes” category. Ceramic membranes belong to “inorganic membranes” category and need to be distinguished with other types such as metallic membranes or other hybrid inorganic membranes.

Membrane Types

Ceramic membranes can be divided to two types: porous and dense. Porous ceramic membranes have found their industrial usages in various filtration processes, while dense membranes are still at stages not more than pilot plants.

Porous ceramic membranes separate substances based on size exclusion; therefore, they can be further categorized as microfiltration, ultrafiltration, and nanofiltration membranes according to the pore size. Dense ceramic membranes separate one or two particular species (usually oxygen or hydrogen) based on the ionic conductivity of membrane materials, and they

often need to be used at high temperatures to increase their ionic conductivity.

Membrane Materials

Porous ceramic membranes are usually used in liquid filtration processes and mostly in aqueous environments; therefore, the membrane material must be compatible with water aside from proper mechanical strength. Most commonly used membrane materials are alumina, titanium oxide, zirconia, and silicon carbide. Alumina is predominant among all ceramic membrane materials because of its availability and relatively low cost, and it also provides strong mechanical properties, inert chemical nature, good thermal stability, and good surface hydrophilicity to the membranes. Zirconia or stabilized zirconia gives similar membrane characteristics as alumina membranes but much better mechanical properties; however, their price is also higher. Titanium oxide has better hydrophilicity and hydrothermal stability than alumina and zirconia, but its mechanical strength is moderate; therefore, titanium oxide is normally used only for the separation layer supported by alumina membrane supports. Silicon carbide membranes are more permeable than other ceramic materials and they often give impressive fluxes, but the major issue is the fabrication cost, which is much higher than others, due to the expensive raw material and extremely high sintering temperatures, as well as the protecting atmosphere required for sintering.

Dense ceramic membranes are used at high temperatures, and these membranes normally are made of ion-conductive materials or mixed ion and electron-conductive materials. For the former ones, an external circuit is needed to pass electrons to compensate the charge of ionic species when ions move from one side to the other side, and work can be done within the external circuit. This is the principle of solid oxide fuel cells (SOFCs), and the dense membrane acts as the electrolyte in a SOFC. For the later ones, electrons can pass the membrane directly, and separation of gas species can be completed by its own. The most important category of ion-conductive

materials is oxygen-ion conductor, for example, fluorite type oxides including fully stabilized zirconia and doped ceria, which are commonly used in SOFC, and perovskite type oxides that can be used alone to separate pure oxygen from air at high temperatures. Another important category is proton conductor, which also have attracted wide interests to use them in SOFC and high-temperature hydrogen separation.

Membrane Structure and Fabrication

Most ceramic membranes use asymmetric structures to obtain good strength and high permeation fluxes, especially for porous membranes, although symmetric structures are also found in dense ceramic membranes. In an asymmetric structure, a relatively thick and porous ceramic supporting layer is used, which is the source of mechanical strength of the membrane, and a thin separating layer is coated/deposited onto the support to provide selectivity for the membrane.

The supporting layer can be formed by extrusion, or by pressing, followed by partial sintering. The support is then coated/deposited with a desired separating layer. Different coating/deposition techniques have been developed for different purposes, such as dip coating and wash coating, sol-gel process, and chemical or physical vapor deposition techniques.

Applications

Porous ceramic membranes have been commonly used in water and wastewater treatment, food and beverage processing, pharmaceuticals, and chemical processing. The most widely used membrane types are microfiltration and ultrafiltration membranes, although the demand of nanofiltration ceramic membranes is also increasing in recent years.

Dense ceramic membranes have not really found their industrial usages, but some pilot plants of oxygen permeable ceramic membranes with a considerable scale are running in the USA and Europe, and some commercial SOFC products

are also available in the market. Some key technical obstacles need to be addressed before these dense ceramic membranes and the membrane-based technologies can enter into industrial usages, such as high-temperature sealing and system stability.

Ceramic Multilayer Membranes

Swachchha Majumdar

Ceramic Membrane Division, CSIR-Central Glass and Ceramic Research Institute, Kolkata, West Bengal, India

A ceramic macroporous substrate is required to build multilayers over the substrates. Separation properties of a multilayer ceramic membrane normally depend upon the microstructure of the top layer (Li 2007). However, there may be necessity of intermediate layers between the macroporous substrate and top layer which give certain advantages like preventing sudden differences in pore size of support and top layer. The multilayering is carried out by a coating technique. When a tubular (or flat) substrate is withdrawn from a suspension or colloidal solution in a well-defined manner, a wet and more or less dense dispersion layer of well-defined thickness covering the substrate can be further processed through drying, calcining, or

sintering (Burggraaf and Cot 1996). In general, the process of multilayering involves preparation of multilayer through colloidal or polymeric sol-gel route. Precursors for colloidal sol-gel process may be organometallic compounds (e.g., aluminum or titanium based). This is hydrolyzed using excess of water. The sol is further peptized at certain temperature. It is also possible to prepare multicomponent sols. Supported gel layers are formed on membrane support by dip coating the supports with freshly prepared sols. Obtained gel layers are dried at room temperature followed by calcinations (Van Gestel et al. 2002).

Surface of the multilayer membrane can also be modified for different applications. Surface modification of hydrophilic γ -Al₂O₃/anatase-TiO₂ multilayer membranes by a silane coupling treatment in order to obtain NF membranes applicable in nonpolar solvents has been studied (Van Gestel et al. 2003).

Multilayer ceramic membranes have got huge potential for gas permeation applications which include separation of CO₂ or H₂ from methane and other hydrocarbons, adjustment of H₂/CO ratio in syngas, separation of air into nitrogen and oxygen, and recovery of helium and methane from biogas. Inorganic membranes also offer profound potential in applications for gas separation in a high-temperature catalytic reaction and are potentially useful for the separation of trace contaminants such as ammonia, hydrogen sulfide, and carbonyl sulfide from coal gasifier fuel gases (Othman et al. 2004).

Ceramic Supported Polymer Composite Membranes in Pervaporation

Wanqin Jin

State Key Laboratory of Materials-Oriented Chemical Engineering, Nanjing University of Technology, Nanjing, China

Ceramic-supported polymer composite membranes in pervaporation are also called polymer/ceramic composite pervaporation membranes and are a type of composite membranes consisting of a thin dense polymeric separation layer and a porous inorganic ceramic support layer (as shown in Fig. 1). Theoretically, the polymeric materials used for preparing composite membranes are also suitable to produce polymer/ceramic composite membranes. For instance, polydimethylsiloxane (PDMS) (Xiangli

et al. 2007) and poly(vinyl alcohol) (PVA) (Zhu et al. 2010) are the typical hydrophobic and hydrophilic membrane materials, respectively. To keep a low transport resistance meanwhile ensures to obtain a defect-free selective layer; the mean pore size of the porous ceramic support ranges from a few nanometers to submicron size.

Like most composite membranes, polymer/ceramic composite membranes possess high selectivity from the polymeric layer and high flux from the porous ceramic support. Compared with traditional polymer composite membranes using organic support, ceramic-supported polymer composite membranes show advantages of chemical, mechanical, and thermal stability. Considering the practical application, the configurations of polymer/ceramic composite membrane usually include tubular and hollow fiber.

Polymer/ceramic composite membrane is always fabricated by dip-coating method in which a certain polymer solution is deposited on the outer or inner surface of the pretreated ceramic support. In general, some key preparing parameters such as polymer molecular weight, polymer concentration, cross-linking degree, dip-coating time, and surface properties of ceramic support play an important role in membrane preparation. The separation performance of polymer/ceramic composite membrane is determined by the integrity of the top polymeric layer and the thickness of the separation layer and interfacial layer created

Ceramic Supported Polymer Composite Membranes in Pervaporation, Fig. 1 Structure and morphology of polymer/ceramic composite pervaporation membrane

by the penetration of polymer solution into the porous ceramic support (Liu et al. 2012).

According to the membrane materials of the polymeric separation layer, the applications of ceramic-supported polymer composite membranes in pervaporation include organic compounds recovery from aqueous solution (Xiangli et al. 2008), biofuel production (Liu et al. 2012), gasoline desulfurization (Xu et al. 2010), solvent dehydration (Zhu et al. 2010), and hybrid process (Liu et al. 2011; Lv et al. 2012). For example, the PDMS/ceramic composite membrane can be applied for pervaporation recovery of ethanol from dilute water solution. With 5 wt.% ethanol/water in the feed at 40 °C, the membrane exhibits a high flux of 1.6–4.5 kg/m²h and separation factor of 6.5–8.5 with ethanol concentration in the permeate of 26–31 wt.%.

CH₄/N₂ Separation

A. Baudot

Physics and Analysis Division, IFP Energies nouvelles, Solaize, France

The US pipeline specification requires an inert content lower than 4 % in natural gas. It is estimated that 14 % of US present proven gas reserves contain more than 4 % nitrogen (Baker and Lokhandwala 2008; Lokhandwala et al. 2010). The most trivial solution consists in diluting small flow rates of nitrogen-concentrated natural gas with main streams of natural gas containing a low concentration in inert gases. However, if this is not feasible (for instance, when all the surrounding gas fields contain high concentrations in nitrogen), it is necessary to install a nitrogen removal plant to comply with the regulatory natural gas composition specifications. Cryogenic distillation is the dedicated technology for large-scale nitrogen removal operations (60,000–600,000 Nm³/h capacity for operation life higher than 10 years). At the very end of the 1990s, 26 such plants were in operation on US ground (Lokhandwala et al. 2010). Two technologies have been recently introduced in order to solve this challenge at small and medium scale: pressure-swing adsorption (PSA) with molecular sieves (*Molecular Gates*® by the Engelhard company (Mitariten 2001, 2004) and gas permeation, which has been promoted by *MTR Inc.* since the end of the 1990s (Lokhandwala et al. 2010).

In the mid-1990s, *MTR Inc.* evaluated at lab scale (on 1–2 m² membrane modules) a wide array of composite membranes which selective membranes were made of various glassy or rubbery polymers (Lokhandwala et al. 2010). Intuitively, rubbery polymers proved to be more selective toward methane (due to its higher sorption, induced by its more condensable behavior than nitrogen), while glassy polymers, especially fluorinated ones, proved to be more selective toward nitrogen (due to diffusive selectivity).

MTR Inc. evaluated the economic feasibility of a membrane-based nitrogen removal operation on a 12,000 Nm³/h natural gas stream entering the process at 32 bar and containing 10 % nitrogen. The target of the membrane operation was to reach the 4 % nitrogen specification in the product gas while the waste gas was containing at least 50 % nitrogen and the overall methane recovery yield was to be higher than 93 %. Based on the performances of the various tested membrane materials, the study led to the conclusion that a single-stage membrane operation was not viable,

whether the membrane material was nitrogen-selective or methane-selective. Therefore, two-stage recycle schemes were studied involving only nitrogen-selective membranes or only methane-selective membranes or a combination of both. Only the use of methane-selective membranes proved to offer interesting performances (Lokhandwala et al. 2010), though the resulting process schemes were leading to significant extra cost due to the presence of two compressors: the first compression unit was used to pressurize the methane-enriched permeate produced by the first

membrane stage to the pipeline pressure, while the second one was aiming at boosting the pressure of the permeate stream issued from the second-stage in order to recycle it at the input of the first membrane stage. With this scenario, the total equipment investment cost was in a 4–8 million US dollar range (in 2009), while the required membrane area was approximately equal to 4,000 m². This appears to be acceptable by gas processors as the payback time of this type of installation was estimated to be 1 year.

The first field test of these membranes was therefore conducted with a 40 in-long module equipped with few m² of methane-selective membranes for more than 1 year on a shut-in gas well containing 15 % nitrogen operated by *Butcher Energy* in Southern Ohio. The performances of the spiral-wound module were very similar to those observed at lab scale, and its permeation properties remained unchanged for the first 6-month period. After this proof of principle, *MTR Inc.* designed different membrane-based nitrogen removal process schemes, trade-named *Nitrosep*[™], with various module/compressor configurations depending on the nitrogen concentration to be addressed (Fig. 1).

Up till now, 12 *Nitrosep*[™] units have been installed in the industry. Few examples depicting the applications addressed by this membranes process are listed hereafter:

- A very small unit was installed in Southern Kentucky in order to upgrade 200 Nm³/h of natural gas containing 7 % nitrogen. This two-membrane module unit was able to recover 80 % of the natural gas with a nitrogen content of 3.8 %. Part of the residue gas was used as compressor engine fuel, while the rest was vented.
- A much larger unit was installed in Rio Vista, California (14,000 Nm³/h treatment capacity). The membrane operation was aiming at upgrading a 16 % nitrogen containing natural gas to a gas stream offering 10 % more heating value (lowering thus the nitrogen content to 9 %). The membrane system involved three stages in series and allowed a methane recovery yield of 95 % for pipeline delivery.

CHA Zeolite Membrane

Tsuneji Sano

Department of Applied Chemistry, Hiroshima University, Graduate School of Engineering, Higashi-Hiroshima, Japan

Zeolites are a class of crystalline aluminosilicates with highly regular and open microporous structures. More than 200 types of zeolite frameworks have been identified by the Structure Commission of the International Zeolite Association. Zeolite membranes combine the great advantages of inorganic membranes, such as temperature stability and resistance against solvents, with the molecular sieving effect.

Zeolite chabazite (CHA, where the three characters indicate the framework type) with Si/Al ratios of 2 ~ 3 is known to possess a three-dimensional pore system with large ellipsoidal cages (6.7 × 10 Å) that are accessible via eight-membered ring windows (3.8 × 3.8 Å). Figure 1 shows the framework structure of CHA zeolite (IZA web. 2013). High-silica CHA (Si/Al ratio > 5) has attracted great interest owing to its thermal and acid stabilities, and hence, application of this material to membrane has been widely investigated. The high-silica CHA zeolite membrane can separate light-gas mixtures of CO/N₂, CO₂/CH₄, H₂/CH₄, and H₂/n-C₄H₁₀ with notably higher selectivity than that allowed by the Knudsen mechanism (Kalipcilar et al. 2002). The high-

CHA Zeolite Membrane, Fig. 1 Framework structure of CHA zeolite (IZA web. 2013)

silica CHA zeolite membrane also exhibits excellent dehydration performance for water/alcohol mixtures (Hasegawa et al. 2010).

As the high-silica CHA zeolite has only been synthesized using expensive *N,N,N*-trimethyl-1-adamantammonium cation (TMAda⁺) as a structure-directing agent (SDA). Very recently, success was achieved in synthesizing high-silica CHA zeolites with Si/Al ratios of 5–21 from FAU zeolite using the benzyltrimethylammonium cation (BTMA⁺) instead of the expensive TMAda⁺. The high-silica CHA zeolite synthesized by the interzeolite conversion of FAU zeolite has superior acid stability (structural and compositional stabilities) as compared to the CHA zeolite synthesized using TMAda⁺ (Yamanaka et al. 2012).

Polycrystalline high-silica CHA zeolite membranes can be formed by the secondary growth of seed crystals on the outer surface of porous supports such as a porous α -alumina tube. Seed crystals are applied to the outer surface of the support tube by rubbing in order to implant the seed crystals for nucleation. The secondary growth solution with a chemical composition of $\text{SiO}_2:0.03\text{Al}_2\text{O}_3:0.2\text{BTMA}:0.1\text{NaCl}:10\text{H}_2\text{O}$ is prepared from the dealuminated FAU, BTMAOH, NaCl, and distilled water. Thereafter, a

hydrothermal reaction is carried out at 130 °C for 7 days using a Teflon[®]-lined autoclave. After cooling the autoclave, the support tube is recovered, washed with distilled water, and dried overnight in air at room temperature. Finally, the support tube is calcined at 550 °C for 20 h. Figure 2 shows scanning electron micrographs (SEM) of the surface and cross section of the CHA membrane on the α -alumina support (Yamanaka et al. 2012). The high-silica CHA-type zeolite membrane prepared on the α -alumina tube is connected with the stainless steel tube using heat shrink tubing, and the tube is subsequently set in the conventional batch-type pervaporation apparatus. An acetic acid aqueous solution (50/50 wt%) is used as the feed at 75 °C. The compositions of the feed and the permeate are determined by FID-gas chromatography (5MS capillary column). The permeation flux and separation factor, $\alpha(\text{H}_2\text{O}/\text{CH}_3\text{COOH})$, are calculated from the following equations:

$$\text{Flux (kg/m}^2\text{ h)} = \frac{(\text{weight of permeate, kg})}{(\text{membrane area, m}^2) \times (\text{permeation time, h})} \quad (1)$$

$$\text{Separation factor } \alpha(\text{H}_2\text{O}/\text{CH}_3\text{COOH}) = \frac{[\text{C}_{\text{H}_2\text{O}}/\text{C}_{\text{CH}_3\text{COOH}}]_{\text{Permeate}}}{[\text{C}_{\text{H}_2\text{O}}/\text{C}_{\text{CH}_3\text{COOH}}]_{\text{Feed}}} \quad (2)$$

where the $\text{C}_{\text{CH}_3\text{COOH}}$ and $\text{C}_{\text{H}_2\text{O}}$ are the weight fractions of acetic acid and water, respectively.

The permeate flux and separation factor, $\alpha(\text{H}_2\text{O}/\text{CH}_3\text{COOH})$, are 7.9 kg/m² h and ca. 2500, respectively, and the membrane performance is identical to that of commercially available NaLTA zeolite membranes used for the dehydration of alcohol solution (Sato et al. 2008). The long-range time courses of both the separation factor and the flux are listed in Table 1 (Yamanaka et al. 2012). The CHA membrane prepared by the interzeolite conversion of FAU zeolites has high potential for use in the separation of water from acidic organic solvents and is not limited to acetic acid.

Membrane characterization is a key part in membrane research and development. In fact, the design of membrane processes and systems depends on reliable data relating to membrane properties. To identify a membrane type to be used for a particular process, it is crucial to know its properties.

Since membranes are very different in their properties and applications, a large number of different techniques are required for their

characterization. Some of the most important membrane characterization procedures described in the literature or recommended by membrane manufacturers are illustrated.

Porous micro- or ultrafiltration membranes are generally characterized in terms of their flux, their pore size, their pore size distribution, and their molecular mass cutoff. Other important characteristics are the nature of the membrane material (whether it is hydrophilic or hydrophobic or carrying positive or negative charges), the structure of the membrane (whether it is symmetric or asymmetric), and their mechanical, chemical, and thermal stability. The methods used to characterize porous membranes include simple filtration and retention measurements, microscopic techniques, surface tension measurements, and the determination of pore radii by liquid/gas or liquid/liquid replacement. The chemical and mechanical stability at various temperatures is usually measured in long-term tests. Which of the membrane characterization methods are applied depends on the use of the membrane.

The Pure Water Flux of Micro- and Ultrafiltration Membranes

A characteristic property of micro- and ultrafiltration membranes is their “pure water flux” or “pure water permeability.” The flux J through a porous medium is proportional to the applied hydrostatic pressure and inversely proportional to the solvent viscosity. It is expressed in Darcy’s law, which is given by:

$$J_v = \frac{L_p \Delta p}{\eta} \quad (1)$$

Here J_v is the membrane flux, L_p is the hydrodynamic solvent permeability, η is the viscosity of the solution passing through the pores of the membrane, and Δp is the applied pressure.

For the determination of the pure water flux, it is very important to use a certain water quality. Generally deionized or distilled water with a conductivity of $<5 \mu\text{S cm}^{-1}$, which is treated by

microfiltration to remove suspended materials, is used as a test solution. The flux is determined at different applied pressures and plotted as a function of the pressure. From the slope of the plot, the hydrodynamic permeability is obtained. Prior to the flux measurements, the membranes should be pressurized by filtration of pure water at a hydrostatic pressure that is at the upper limit of the recommended operating pressure for one to two hours to compress the membrane to a stable value that will not further deform when used at lower pressures. Possible preservatives, often present in membranes, must be eliminated by a washing procedure.

Some inorganic membranes, like Al_2O_3 -based types, show an apparent internal pore clogging when deionized water is used in the pure water flux measurements. In these cases an electrolyte solution is used for determining the membrane flux, e.g., a NaCl or KCl solution. Since there exists no standard method for the determination of the pure water flux, companies use their own standards, which makes a reliable comparison of pure water fluxes rather difficult.

Typical pure water fluxes of microfiltration membranes vary from 500 to 50,000 $\text{L m}^{-2} \text{h}^{-1} \text{bar}^{-1}$, while pure water fluxes of ultrafiltration membranes vary from 50 to 800 $\text{L m}^{-2} \text{h}^{-1} \text{bar}^{-1}$.

In practical applications, fluxes are normally much lower, and a steep flux decline is observed during the first period of operation. This flux decline is mainly determined by membrane fouling which is generally more pronounced for microfiltration than for ultrafiltration.

Microscopic Techniques

A variety of microscopic techniques are used to study membrane structures, such as scanning electron microscopy, field emission electron microscopy, transmission electron microscopy, and atomic force microscopy. The advantage of these techniques is that direct visual information of the membrane morphology is obtained. The different microscopic techniques require different preparation methods and have different resolution. Scanning electron microscopy, e.g., has a resolution of

up to 5 nm and provides good information on the structures of micro- and ultrafiltration membranes including pore sizes and pore shapes. To reach a high resolution, high electron beam energy has to be applied, which can damage the membrane samples. Another problem is that in electron microscopy, a conductive layer must coat the samples. This is generally done in a high vacuum, which can lead to a change of the structure of membranes made from hydrophilic polymers.

The pore sizes and pore shapes of ultrafiltration membranes can also be determined by transmission electron microscopy which has a resolution of 0.4–0.5 nm or by field emission electron microscopy which has a resolution of 0.6–0.7 nm. The transmission electron microscopy technique requires a significantly more complex preparation procedure and is mainly applied to determine the surface porosity of ultrafiltration membranes (Fane et al. 1981). Because of the high resolution, pores in ultrafiltration membranes can be visualized by field emission electron microscopy (Kim et al. 1990).

Sample preparation for scanning electron microscopy and field emission electron microscopy analysis is relatively easy compared to the sample preparation for transmission electron microscopy. To visualize the cross sections of a membrane, e.g., it is immersed in ethanol or a water/ethanol mixture prior to cooling in liquid nitrogen. The sample is fractured providing a rather clean fracture and glued with conductive glue to a sample holder and sputtered with a thin layer of gold. The sputtered layer should be thinner than the structure features of the membrane to be studied. Recently, low-vacuum scanning electron microscopy, i.e., so-called environmental scanning electron microscopy, has become available which makes it possible to scan a sample without a conductive coating. However, the resolution of these microscopes is limited to magnifications of ca. 7500. Figures 1 and 2 show typical pictures of membrane structures that can be obtained by scanning electron microscopy techniques.

Besides electron microscopy, atomic force microscopy is also applied to study membrane surface structures. Atomic force microscopy has

a resolution of ca. 1 nm (Fritzsche et al. 1992; Hilal and Johnson 2010). Sample preparation is fairly simple, since no conductive coating is required. Therefore, samples need not be dried and exposed to vacuum. AFM can operate in air and liquid phases; therefore, membranes can be studied in the environments used during their operation. This is very valuable for determining influence of physical-chemical parameters (such as pH, ionic strength, charge) and functional molecules on membrane surface properties.

The Mechanical Properties of Membranes

The mechanical stability and swelling behavior of the membranes is determined by the degree of cross-linking or crystallinity of the polymer matrix and the concentration of the fixed charges. The structure of membranes based on a highly crystalline polymer such as the fluorocarbon polymers are studied using transmission electron microscopy and small angle X-ray diffraction (Gierke et al. 1982). The degree of cross-linking is closely related to the swelling behavior and the mechanical properties of the membranes. But it also affects the permselectivity. Infrared spectroscopy measurements can provide some information on the type and degree of cross-linking of ion-exchange membranes.

A mechanical characterization of ion-exchange membranes involves the determination of its swelling and dimensional stability in different test solutions and tensile strength and hydraulic permeability measurements. All mechanical characterization tests should be carried out with well-equilibrated membranes in a controlled environment. The tensile strength and information concerning the plastic or elastic deformation of a membrane is obtained from a stress versus strain diagram as shown schematically in Fig. 2.

The strain versus stress curves of ion-exchange membranes generally show three distinct areas. At relatively low strain, the membranes show elastic deformation; with increasing strain, the membranes show plastic deformation, and at a certain point they break. Since the mechanical properties

C

Characterization of Porous and Dense Membranes, Fig. 1 Scanning electron micrographs of (a) a sintered membrane prepared from a polymer powder, (b) a membrane prepared by stretching an extruded polytetrafluoroethylene film perpendicular to the direction of extrusion, (c) of a capillary pore polycarbonate membrane made by

track etching, (d) a porous cellulose nitrate membrane prepared from a homogeneous polymer solution by water vapor precipitation, and (e) a porous polypropylene membrane precipitated by thermal gelation from a hot polymer solution

of membranes generally change drastically with the water content of the membranes, they must be determined with dry membranes and with

membranes equilibrated in water or different solutions similar to those used in practical applications.

Characterization of Porous and Dense Membranes,

Fig. 2 Stress versus strain diagram of a membrane sample indicating the elastic and plastic deformation and the breakpoint

The swelling of membranes depends on a number of different parameters such as the nature of the basic membrane polymer, the nature of the ion-exchange groups and their concentration in the membrane, the counterions, the cross-linking density, the homogeneity of the membrane, and the composition of the solution with which the membrane is in contact. Especially the concentration of the solution has a significant effect on the water sorption of the membrane because of osmotic effects that are directly related to the chemical potential difference of the water in the membrane and in the solution. The state of the water in the membrane can also be rather different. Part of the water is so-called “free” water. Another part of the water is strongly bound within the hydration shell of the counterions and the fixed charges of the membrane, while again another part is more loosely bound to the basic polymer matrix. The different water structures in ion-exchange membranes are studied by differential scanning calorimetry, infrared spectroscopy, and nuclear magnetic resonance (Komorowski and Mauritz 1982). Studies of the water structure within the membrane and its interaction with the membrane polymer, fixed charges, and counterions require more sophisticated spectroscopic measurements. The total water uptake of the membrane in equilibrium with an electrolyte solution, however, can be determined quite easily by measuring the weight difference between a membrane in the wet and dry state. To determine the

water content of a membrane, a sample is equilibrated in a test solution. After removing the surface water from the sample, the wet weight of the swollen membrane is determined. The sample is then dried at elevated temperature over phosphorus pentoxide under reduced pressure until a constant weight is obtained. The water content of a membrane is obtained in weight percent by:

$$\text{wt\% swelling} = \frac{W_{\text{wet}} - W_{\text{dry}}}{W_{\text{wet}}} \times 100 \quad (2)$$

Here W_{wet} and W_{dry} are the weight of a membrane sample in the wet and the dry state.

Membrane Separation Properties Determined by Filtration Test

Both micro- and ultrafiltration are pressure-driven membrane processes using porous membranes. The separation of various components is based on a sieving mechanism, i.e., this membrane retains particles or molecules that are larger in size than the pores of a membrane. A relation as a function of the particle size and the pore size for the membrane retention can be defined by a relation between the pore and the particle radius (Ferry 1936). If the particles are spherical and have a radius r_s and the membrane pores are cylindrical with a radius r_p , the following relation can be applied to describe the membrane solute rejection:

$$R = \left[1 - \left(1 - \frac{r_s^2}{r_p^2} \right) \right]^2 \quad (3)$$

For the radius of the molecule, either the radius of gyration or the hydrodynamic radius can be used. The Ferry model is rather simplified, but gives a good approximation of the expected retention when particle size and the membrane pore radius are known.

Retention and Molecular Weight Cutoff

To describe the retention of ultrafiltration membranes, usually the molecular weight cutoff is used. The molecular weight cutoff determination is very sensitive to the experimental conditions, i.e., the solutes and their concentration used in the test, the applied pressure, and the temperature. Therefore, a comparison of retention data given by different manufacturers is generally problematic. As test conditions for determining the ultrafiltration membrane cutoff, a transmembrane pressure of 100 kPa, a feed solution concentration of 0.1 %, and a test temperature of 25 °C are recommended. Furthermore, a maximum of agitation of the feed solution at the membrane surface is required to minimize concentration polarization effects, and small amounts of solution should be filtered to assure a constant feed concentration.

The retention is generally expressed in % and defined by:

$$R = \left(1 - \frac{C_p}{C_f} 100 \right) \quad (4)$$

Here R is the retention or rejection of a membrane and C_f and C_p are the feed and the permeate concentration.

The retention of molecules having identical molecular weights may be rather different when their shape is different. Globular proteins, e.g., are rejected easier than branched polysaccharides or flexible polymers (Porter 1979). Adsorption of the solute to the membrane surface, e.g., might result in high “apparent” retention values when

the experiment is performed for a very short time period. Accumulation of solutes at the membrane surface due to concentration polarization effects can also obscure the retention measurements and must be considered when the true, i.e., intrinsic, retention shall be determined. Using low pressures, low feed concentrations, and a high degree of agitation can more or less eliminate these effects.

Manufactures of ultrafiltration membranes generally make use of marker molecules, e.g., dextrans and proteins, for the determination of the molecular weight cutoff value of their membranes. In addition to the molecular weight cutoff of a membrane, the sharpness of the cutoff is important for the practical application. The sharpness of the cutoff of a membrane is determined by measuring the retention of the membrane for components of different molecular weights and plotting the retention versus the molecular weight of the retained components. The sharpness of the cutoff of a membrane depends mainly on the pore size distribution of the membrane. For practical applications, the cutoff of a membrane should be as sharp as possible.

The Bacterial Challenge Test

Micro- and ultrafiltration membranes are often used in the food and pharmaceutical industry for the sterilization of solutions. In this application, it is important that membranes retain undesired microorganisms as completely as possible, i.e., the retention for microorganisms should be close to 100 %. Therefore, these membranes are exposed to a bacterial challenge test. In this test, the membrane is challenged with a solution containing a minimum concentration of organisms such as *Pseudomonas diminuta* per cm³ of solution (Cheryan 1998). The data obtained in bacterial challenge tests are normally expressed in terms of the log reduction value, which is given by the logarithms of the ratio of feed to filtrate concentration. The bacterial challenge test is a destructive test and is therefore not suited as an on-line quality control test. For this application, the nondestructive diffusion test and the bubble point integrity test are generally applied.

Characterization of Porous and Dense Membranes,

Fig. 3 Schematic drawing that illustrates the capillary effect of a membrane pore

Membrane Properties Determined by Membrane Pore Size Measurement

In addition to filtration tests, micro- and ultrafiltration membranes are characterized by determining their pore size and pore size distribution. A number of techniques such as liquid/gas and liquid/liquid displacement, mercury intrusion, permporosimetry, thermoporosimetry, etc. are used for the determination of the membrane pore size and pore size distribution. One of the more simple methods is the so-called bubble point test.

The Bubble Point Test

The bubble point test is a structure integrity test in which the largest pore or hole in a membrane is determined. The bubble point method is based on the capillary effect of small pores due to surface tension forces. In equilibrium these forces are balanced with gravity of the liquid in the pores. The principle is shown in Fig. 3.

This equilibrium between surface tension forces and gravity of the liquid in the pore can be expressed by the following equation:

$$2\pi r_p \sigma \cos \phi = r_p^2 \pi h \rho g \quad (5)$$

Here r_p is the pore radius, σ is the surface tension of the liquid in contact with air, $\cos \phi$ is the contact angle between the liquid and the wall of the pore, h is the height of the liquid column, ρ is liquid density, and g the acceleration of gravity.

The term $h \rho g$ in Eq. 5 can be replaced by the pressure p . This results in the Laplace equation, which is given by:

$$r_p = \frac{2\sigma \cos \phi}{p} \quad (6)$$

The bubble point method is a fairly simple technique where the pores of a membrane are filled with a liquid. From the bottom side of the membrane, nitrogen gas or air is introduced with increasing pressure. At a certain pressure, the gas will replace liquid in the largest pores permeating the membrane, and a bubble rising from the membrane surface can be observed.

Equation 6 referred to as Laplace equation gives a relation for the surface tension between the liquid and the gas and the required pressure to open up pores of a certain size. In the bubble point test, mostly water or isopropanol is used, since the surface tension of water/air is approximately 3.5 times higher than for isopropanol/air.

Other techniques to determine the pore size and pore size distribution of a porous membrane that are also based on the Laplace equation, but cover different pore size ranges when the same pressure range is applied, are mercury porosimetry, gas-liquid displacement, and liquid-liquid displacement.

The Mercury Porosimetry

In mercury porosimetry, a dry membrane is exposed to a certain volume of liquid mercury.

Characterization of Porous and Dense Membranes,

Fig. 4 Schematic drawing illustrating the gas/liquid displacement measurement to determine the pore size and pore size distribution of microfiltration membranes

The pressure applied to the mercury is slowly increased, while simultaneously the amount of mercury forced into the porous structure is measured. The largest pores will be filled first and the required pressure for the mercury to penetrate the porous structure increases with decreasing pore size. The required pressure corresponds to a certain pore radius and the amount of mercury that disappears in the membrane corresponds to the total volume of these pores. The interfacial tension of mercury and air is very high. Therefore, relatively high pressures are required to fill small pores. In polymer membranes, only pores having a radius in excess of 1 μm can be detected reliably by mercury porosimetry. Furthermore, this technique does not give distinction between dead-end pores and interconnected pores.

Gas-Liquid Displacement

The gas-liquid displacement technique is identical to the bubble point method. The pores of the membrane are generally filled with an organic solvent which has a lower surface tension than water. The solvent is forced out of the membrane pores by nitrogen gas, which is introduced with increasing pressure. As the pressure increases, the liquid will be replaced by nitrogen in the largest pores first, and a convective gas flow through these pores will occur. The gas flow is measured as a function of the applied pressure. When all the pores are opened, a linear relationship between

pressure and gas flow is observed when the pressure is further increased. Figure 4 shows schematically typical gas fluxes obtained as a function of pressure with a dry and a liquid-filled membrane.

The mean flow pore size is given by the point where the 50 % “dry” flow curve crosses the “wet” flow curve. The maximum pore size is given by the point where a first flow through the liquid-filled membrane is observed. The minimum pore size is given by the point where the fluxes of the dry and the liquid-filled membrane become identical. The Laplace equation describes the relationship between the pore radius and the applied pressure.

Liquid-Liquid Displacement

Liquid-liquid displacement differs from gas-liquid displacement in the displacing medium; a second liquid instead of a gas displaces the liquid inside the pores. The two liquids applied should be immiscible. A typical liquid pair used is water/isobutanol. Both liquids are first saturated with each other before one of the liquids is used to fill the pores and the other liquid is applied as replacement liquid. The experimental setup for the determination of pore sizes by liquid-liquid displacement is shown in Fig. 5. A slow increase the replacement liquid pressure pushes the liquid out of the largest pores first. With increasing in pressure, the liquid in the smaller pores will also be replaced. The pore size distribution can be

Characterization of Porous and Dense Membranes, Fig. 5 Schematic representation of a typical liquid-liquid displacement setup (Capannelli et al. 1983)

calculated from a plot of the flux versus the applied pressure (Capannelli et al. 1983; Wienk et al. 1994).

Whether isobutanol or water is used as displacing liquid depends very much on the nature of the membrane material. Due to swelling phenomena, different results might be obtained depending on the liquid placed inside the pores.

The relation between the pore radius and the pressure required to open pores of a certain size is again described by the Laplace equation, and the pore size distribution can now be calculated when the flux as a function of the pressure is measured.

Like in gas-liquid displacement, only active pores contributing to transport are taken into account. Pore diameters of approximately 5–100 nm can be analyzed using liquid-liquid displacement. The advantage of liquid-liquid displacement over gas-liquid displacement is the lower interfacial tension between liquid pairs compared to a gas/liquid pair. Therefore, pores of the same size can be opened at much lower pressures in liquid-liquid displacement.

There are more methods that can be used to determine pore sizes in porous membranes (Cuperus et al. 1992a, b) such as permoporometry or thermoporometry, which is based on the microcalorimetric analysis of a solid-liquid transition

using a sensitive differential scanning calorimetry. Permoporometry is a technique based on gas adsorption/desorption measurements where pores are either filled by controlled condensation of a vapor phase or where filled pores are emptied by controlled evaporation of the liquid inside the pores. The relation between the relative vapor pressure and the pore radius is given by the Kelvin equation. Thermoporometry is based on the microcalorimetric analysis of a solid-liquid transition using a sensitive differential scanning calorimetry.

Table 1 shows the pressures required to open pores of 10 nm for different displacement systems. A second advantage is that membranes are characterized in a wetted state, and therefore the test conditions are closer to the real operating conditions.

Dense Membrane Characterization

Dense membranes are generally used for the separation of low molecular mass materials such as gases, salts, or solvents. The transport mechanism in these membranes is based on the solution and diffusion of components within the membrane matrix. The intrinsic properties of the basic membrane material are often more relevant for

Characterization of Porous and Dense Membranes,**Table 1** Different porosimetry techniques and the influence of the interfacial tension on the pressure required opening pores of 10 nm

Technique	System	Pressure	
		(mN/m)	(Bar)
Mercury porosimetry (G-L)	Air/mercury	480	749
Bubble point (G-L)	Air/water	72.3	145
Coulter porometry (G-L)	Air/Porofil®	16	32
Gas-liquid displacement (G-L)	Air/isobutanol	20.7	41
Liquid-liquid displacement (L-L)	Water/isobutanol	1.85	3.7
Liquid-liquid displacement (L-L)	Water/isobutanol/methanol	0.35	0.7

characterizing their transport behavior than is the macroscopic membrane structure. Characterization methods used with microporous structures have therefore been supplemented with other procedures, such as sorption and diffusion measurements or determination of the glass transition temperature and crystallinity of the basic membrane material. For ion-exchange membranes, the measurement of electrokinetic properties is required.

In addition to the determination of diffusion and partition (solubility) coefficients, measurements providing information on the physical structure of the polymer, such as differential scanning calorimetry, X-ray studies, or determination of the free volume in a polymer, are important. These methods are described in Koros and Chem (1987), Berens and Hopfenberg (1982), and Morel and Paul (1982). Permeability and selectivity are the most interesting parameters; they are determined in permeation tests and expressed in terms of rejection coefficients (in reverse osmosis) or separation coefficients (in gas separation and pervaporation). These coefficients are usually not constant but a function of composition, temperature, and pressure. Furthermore, boundary layer effects at the membrane surface often obscure the determination of membrane fluxes and selectivities in practical measurements.

The methods used to determine the structural properties of ion-exchange membranes are similar to those used for characterizing other polymer membranes. Because ion-exchange membranes are used mainly in separation processes with electrical potential driving forces, their permeability and selectivity are determined under experimental conditions closely related to their practical use, and their properties are expressed in terms commonly used in electrochemistry (e.g., electrical resistance, ion-transfer numbers, charge densities) (Cussler 1971, 1984).

Charged Ultrafiltration Membrane

Andrew L. Zydney
Department of Chemical Engineering,
The Pennsylvania State University,
University Park, PA, USA

Electrically charged ultrafiltration membranes can be used to reduce the fouling and increase the retention of like-charged species. Most polymeric membranes have a net negative charge in solution due to the presence of trace anionic groups (e.g., carboxylic acids) and/or the preferential adsorption of negatively charged ions from the aqueous solution. It is also possible to cast membranes from polymers containing fixed charge groups, e.g., a positively charged membrane can be developed using polymers containing fixed amine groups. However, the most common method for generating charged ultrafiltration membranes is by surface modification of a base polymer through the attachment of appropriate anionic (e.g., carboxylic or sulfonic acid) or cationic (e.g., quaternary amine) groups. The overall performance of these membranes is determined by the density of the charge

groups, the chemistry of the ligand and the covalent linkage, and the properties of the spacer arm used to attach the ligand to the membrane (Zydney 2011).

One of the first applications of charged ultrafiltration membranes was in the recovery of electropaint. Electrodeposition of a charged paint resin is used extensively in the industrial painting of metallic surfaces in automobiles and large household appliances. The paint resins are organic polymers with attached anionic or cationic groups. Ultrafiltration has been used to recover the charged electropaint from the dilute solution produced by washing the excess paint off of the metal part. Ultrafiltration can also be applied directly to the paint in the electrodeposition bath, with the permeate (essentially water) used for subsequent rinsing steps (Zeman and Zydney 1996). The use of charged membranes (having the same polarity as the electropaint) provides significantly greater filtrate flux with less fouling than neutral or oppositely charged membranes.

Charged ultrafiltration membranes can be used to significantly improve the inherent tradeoff between the permeability and selectivity of an ultrafiltration membrane (Mehta and Zydney 2005). The rate of solute transport through a charged ultrafiltration membrane is determined by a combination of steric (size based) and electrostatic interactions (Mehta and Zydney 2006). Electrostatic interactions strongly effect the partitioning of charged solutes into the membrane pores. For example, the presence of positively charged groups on the pore surface causes a strong electrostatic exclusion of positively charged species from the membrane pores significantly increasing the selectivity of the membrane. This makes it possible to employ charged ultrafiltration membranes with relatively large pore size and thus with very high permeability, with the required selectivity achieved by electrostatic exclusion of the protein.

There is also considerable interest in performing protein separations by charged UF membranes. In this case, the charged ultrafiltration membrane provides very high retention of like-charged proteins, enabling uncharged proteins and smaller impurities to be washed into the permeate by a diafiltration process (see Fig. 1). The solution pH and ionic strength can be adjusted to obtain high-resolution

Charged Ultrafiltration Membrane, Fig. 1 Positively charged membrane provides high retention of positively charged protein while allowing transmission of neutral proteins

protein separations (van Reis et al. 1999). Van Reis and Zydney (2007) have discussed a number of separation processes using charged ultrafiltration membranes, including a nonaffinity process for purifying a monoclonal antibody from harvested cell culture fluid.

Equilibrium in a system is achieved when all components are in the same thermodynamic state, i.e., the Gibb's free energy of the system is constant. Equilibrium between two systems such as a membrane and an adjacent solution or two solutions separated by a membrane is obtained when both

systems are in the same thermodynamic state, i.e., when the Gibb's free energies in both systems are identical. The Gibb's free energy of a system is a function of various state variables such as pressure, electrical potential, and the activity of individual components. A system composed of water and an electrolyte which is partially dissociated will be in equilibrium when dissociated and non-dissociated components are in equilibrium. Considering two systems separated by a membrane which is impermeable to some components and permeable to others, the two systems will be in equilibrium when all components that are able to permeate the membrane have identical electrochemical potentials in both systems. This may also be the case if the components do have differences in pressures, electrical potentials, or the activities in the two systems as long as these differences compensate each other and the sum of the state variables, i.e., the Gibb's free energy in both systems is identical. Examples for two systems being in equilibrium are the osmotic equilibrium, in which pressure and activity differences compensate each other, and the Donnan equilibrium which is obtained when an electrical potential difference is compensated by activity difference. For membrane processes, the dissociation equilibrium in a system as well as the osmotic and the Donnan equilibrium between two systems are of importance and will be discussed in more detail.

Water is dissociated to a certain extent into hydronium and hydroxide ions, i.e., H_3O^+ and OH^- ions according to the following equilibrium relation:

The water dissociation equilibrium constant K is

$$\frac{[\text{H}_3\text{O}^+][\text{OH}^-]}{[\text{H}_2\text{O}]^2} = K \quad (2)$$

The brackets $[\]$ denote concentrations of the various components in equilibrium.

In pure water, the concentration of water is 55.6 mol L^{-1} . The product of $K \times [\text{H}_2\text{O}]^2$ is constant and referred to as the water dissociation

product K_w which is $1.008 \times 10^{-14} [\text{mol}^2 \text{L}^{-2}]$ at 25°C (Atkins 1990). It is

$$\begin{aligned} [\text{H}_3\text{O}^+][\text{OH}^-] &= K [\text{H}_2\text{O}]^2 = K_w \\ &= 10^{-14} \text{ (at } 25^\circ\text{C)} \end{aligned} \quad (3)$$

The K_w value is a function of temperature. However, at constant temperature and in electrolyte solutions with low to moderate ion concentrations, the water concentration does not change very much and K_w can be considered constant, and in pure water, the concentrations of H_3O^+ and OH^- ions are identical and are $10^{-7} [\text{mol L}^{-1}]$ at 25°C .

In electrolyte solutions containing an acid or a base, the concentrations of H_3O^+ and OH^- ions are no longer identical, and their concentrations are expressed by the so-called pH value (*potentia hydrogenii*). The pH value is defined as the negative logarithm of the H_3O^+ -ion concentration to the basis of 10. Thus, is

$$[\text{H}_3\text{O}^+] = 10^{-\text{pH}} \quad (4)$$

and

$$[\text{OH}^-] = 10^{-(14-\text{pH})} \quad (5)$$

Pure water or neutral electrolyte solutions at 25°C have a pH value of ca 7. Acid exhibits pH values <7 and bases >7 .

An important parameter for acids and bases is the dissociation constant expressed in the so-called pK value. The dissociation of acids and bases follows the general scheme:

Here, K_1 and K_2 are the dissociation equilibrium constants, and HA and BOH represent the non-dissociated acid and base.

The acid and base equilibrium can be expressed by the following relations:

$$\frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}]} = K_1[\text{H}_2\text{O}] = K_a \quad (8)$$

Chemical and Electrochemical Equilibrium in Membrane Systems, Fig. 1 Schematic drawing illustrating the osmotic phenomenon. It shows two systems (') and (') separated by a semipermeable membrane. The

phases consist of a solvent and a solute indicated by the subscripts l and s . C and μ refer to concentration and chemical potential, p to hydrostatic, and π to osmotic pressure, respectively, and J to the membrane flux

and

$$\frac{[B^+][OH^-]}{[BOH]} = K_2 = K_b \quad (9)$$

Here, K_a and K_b are the dissociation constants for the acid and the base.

The dissociation constant between strong and weak acids or bases can vary by several orders of magnitude. Therefore, the dissociation constant is generally expressed by the so-called pK_a and pK_b values which are defined similarly to the pH value as the negative logarithm of the dissociation constant, i.e.,

$$pK_a = -\log K_a = 10^{-pK_a} \quad (10)$$

and

$$pK_b = -\log K_b = 10^{-pK_b} \quad (11)$$

Multivalent acids or bases such as H_2SO_4 or $Ca(OH)_2$ which have more than one dissociable proton or hydroxide ion dissociate in consecutive steps and, therefore, have more than one pK_a or pK_b value, respectively.

In practical applications the degree of dissociation of an electrolyte is of interest. It is defined as the ratio of dissociated molecules to the total

number of molecules present in a solution and given by:

$$\alpha = \frac{[A^-]}{v_{A'}[AB] + [A^-]} = \frac{[B^+]}{v_{B'}[AB] + [B^+]} \quad (12)$$

Here, α is the dissociation degree and AB is the total concentration of the non-dissociated electrolyte. A^- and B^+ are anion and cation concentrations.

The degree of dissociation α has values between 1 for a totally dissociated electrolyte and 0 for a completely non-dissociated electrolyte.

From practical experience, it is well known that the degree of dissociation of weak acids or bases depends on the pH value of the solution. In solutions with high pH values, weak acids have a higher degree of dissociation than in solutions with low pH values.

If two aqueous salt solutions of different concentrations are separated by a membrane which is permeable for the solvent, e.g., water, but impermeable for the solute, e.g., salt, a transport of water from the more dilute solution in the more concentrated solution is observed. This phenomenon, which is illustrated in Fig. 1, is referred to as osmosis.

The figure shows a schematic diagram of a membrane separating two solutions consisting of a solvent, e.g., water, and a solute, e.g., a salt. The two solutions are indicated by (') and ("). The membrane is assumed to be permeable to the solvent but impermeable to the solute. Depending on the concentrations and hydrostatic pressures in the two phases separated by the membrane, four different situations can be distinguished:

- The hydrostatic pressures in the two phases separated by the membrane are equal, but the solute concentration in solution (') is higher than the one in solution ("). In this case, the osmotic pressure in solution (') is higher than that in solution ("), and there will be a flow of solvent from the more diluted solution (") into the more concentrated solution ('). This situation is referred to as *osmosis*.
- The two phases separated by the membrane have different hydrostatic pressures, but the difference in hydrostatic pressure is equal to the difference in the osmotic pressures between the two solutions acting in opposite direction. This situation is referred to as *osmotic equilibrium*, and there will be no flow of solvent through the membrane, although the concentrations in the two solutions are different.
- The two phases separated by the membrane have different hydrostatic pressures, but the difference in hydrostatic pressure across the membrane is larger than that in the osmotic pressure and is acting in opposite direction. Thus, solvent will flow through the membrane from the solution (') with the higher solute concentration into the solution (") with the lower solute concentration. This phenomenon is referred to as *reverse osmosis*.

The flux of solvent between two homogeneous solutions of different concentrations separated by a semipermeable membrane, which is only permeable for the solvent, to the more concentrated solution as a function of a hydrostatic pressure applied is illustrated in Fig. 2. Here, the solvent flux between two solutions of different concentrations through a strictly semipermeable membrane

Chemical and Electrochemical Equilibrium in Membrane Systems, Fig. 2 Solvent flux between two solutions of different concentrations through a strictly semipermeable membrane as function of the hydrostatic pressure applied to the more concentrated solution

is shown as a function of the hydrostatic pressure applied to the more concentrated solution.

As long as the applied hydrostatic pressure is lower than the osmotic pressure, the difference between the two solutions' solvent will flow from the more dilute solution into the more concentrated solution by osmosis. When the hydrostatic pressure exceeds the osmotic pressure difference, the flow is reversed and solvent will flow from the more concentrated solution to the dilute solution.

The osmotic pressure of a solution π is proportional to the solute concentration. It can be calculated, however, from the activity of the solvent in a solution and is given by:

$$P^S - P^l = \pi = \frac{RT}{V_l} \ln a_l^s \quad (13)$$

For dilute solutions, the osmotic pressure can be expressed to a first approximation by the concentration of the individual components in the solution (Strathmann 2004):

$$\pi = RT \sum_i g_i C_i \quad (14)$$

If the solute is a salt, as is the case in many practical applications, the concentration of the individual ions must be considered when

determining the osmotic pressure, i.e., the degree of dissociation, and the stoichiometric coefficients of the salt have to be considered for determining the osmotic pressure.

The osmotic pressure of an aqueous solution with salts is given by (Robinson and Stokes 1959):

$$\pi = RT \sum_i g_i (v_{ic} + v_{ia}) C_{is} \quad (15)$$

Here, g is the osmotic coefficient; the subscripts v , c , and a refer to a stoichiometric coefficient, cation, and anion.

In discussing the osmotic pressure, it was assumed that two solutions separated by a membrane are in chemical equilibrium. If the solution contains charged components, i.e., ions, and the membrane is permeable for at least one ionic component, the membrane will be in equilibrium with the adjacent solution if the electrochemical potential of all ions in the membrane and the solution are equal. Thus, for each ion in equilibrium, it is

$$\tilde{\mu}_i^m = \tilde{\mu}_i^s = \mu_i^m + z_i F \varphi^m = \mu_i^s + z_i F \varphi^s \quad (16)$$

Here, μ_i and $\tilde{\mu}_i$ are the chemical and the electrochemical potential of the component i , φ is the electrical potential, and F is the Faraday constant. The superscripts m and s refer to the membrane and to the solution, respectively.

Thus, the electrochemical potential of an ion is composed of two additive terms. The first is the chemical potential and the second is the electrical potential multiplied by the Faraday constant and the valence of the ion. Introducing the chemical potential $\mu_i (d\mu_i = \bar{V} dp_i + RT d \ln a_i)$ into Eq. 16 and rearranging gives the electrical potential difference between the membrane and the adjacent solution (Donnan and Guggenheim 1932) to

$$\varphi^m - \varphi^s = \frac{1}{z_i F} \left[RT \ln \frac{a_i^s}{a_i^m} + \bar{V} (p^s - p^m) \right] = \varphi_{Don} \quad (17)$$

Here, φ is the electrical potential, a is the ion activity, $\bar{V}$ is the partial molar volume, z is the valence, F is the Faraday constant, p is the pressure, T is the absolute temperature, and R is the gas

constant; the subscript i refers to individual components and the superscripts m and s refer to the membrane and the electrolyte solution, respectively. The potential difference between the membrane and the solution is referred to as Donnan potential φ_{Don} .

The Donnan potential between an electrolyte solution and an ion exchange membrane cannot be measured directly. It can, however, be calculated from the ion activities in the solution and the membrane and by the pressure difference between the membrane phase and the adjacent solution, $p^m - p^s$, which is referred to as swelling pressure and which is identical to the osmotic pressure difference between the solution and the membrane.

Introducing the osmotic pressure into Eq. 17 gives the Donnan potential as a function of the ion and the water activities in the membrane and the solution:

$$\varphi_{Don} = \frac{1}{z_i F} \left[RT \ln \frac{a_i^s}{a_i^m} - \bar{V}_i \Delta \pi \right] \quad (18)$$

The numerical value of the Donnan potential φ_{don} can be calculated either from the cation or anion activities. For a single salt, thus is

$$\begin{aligned} \varphi_{Don} &= \frac{1}{z_c F} \left[RT \ln \frac{a_c^s}{a_c^m} - \bar{V}_c \Delta \pi \right] \\ &= \frac{1}{z_a F} \left[RT \ln \frac{a_a^s}{a_a^m} - \bar{V}_a \Delta \pi \right] \end{aligned} \quad (19)$$

Equation 19 gives a general relation for the cation and anion distribution at the interface between a solution and an ion exchange membrane.

It should be noted that the value of the Donnan potential is negative for the cation exchange membrane and positive for the anion exchange membrane in equilibrium with a dilute electrolyte solution.

The Donnan equilibrium describes the electrochemical equilibrium of an ion in an ion exchange membrane, and an adjacent solution and can be calculated for a single electrolyte by rearranging Eq. 19:

$$\left(\frac{a_a^s}{a_a^m} \right)^{\frac{1}{z_a}} \left(\frac{a_c^m}{a_c^s} \right)^{\frac{1}{z_c}} = e^{-\frac{\Delta \pi \bar{V}_s}{RT z_c v_c}} \quad (20)$$

Here, z is the valence, ν is the stoichiometric coefficient of the electrolyte, F is the Faraday constant, R is the gas constant, T is the absolute temperature, $\bar{V}$ is the partial molar volume, and a is the activity; the subscripts a and c refer to anion and cation, and the superscripts s and m refer to the solution and the membrane, respectively.

The Donnan equilibrium is an important relation in electro-membrane processes since it determines the distribution of co- and counterions between the membrane and the adjacent solution.

The immobilization in electropolymerized polymers such as polypyrrole has been developed for a variety of biomolecules and provides

Chemical Binding of Biomolecules to Membranes, Fig. 1 Scheme of synthesis of amino propyl pyrrole

very stable environment for the biocatalyst. The advantages of the polypyrrole are the control of film thickness and its contribution in electron transfer between the biocatalysts and the conductive support.

Amino pyrrole is synthesized according the following scheme (Fig. 1).

Electropolymerization of 1-(2-cyanoethyl)pyrrole monomer (1) in acetonitrile 0.1 M NBu_4PF_6 was performed by controlled-potential oxidation of the pyrrole at +1.01 V vs. SCE. Reduction of the nitrile to amine function was carried out using a large excess of LiAlH_4 in dried ether at room temperature.

Enzyme is grafted on the modified tube (with amino polypyrrole) by using glutaraldehyde as coupling agent (Fig. 2).

Fixation of laccase (enzyme which catalyzed the oxygen reduction) on the modified electrode has been investigated and applied to the fabrication of biocathode for enzymatic biofuel cell (Servat et al. 2007).

Chemical Cleaning of Membranes

C. V. Vedavyasan
Department of Technology, Annamalai
University, Chidambaram, Tamil Nadu, India

Introduction

Cleaning of membranes is carried out to enhance its permeability followed by performance in a membrane-based treatment plant. The Pareto principle – 80/20 rule – that 80 % of effects result from 20 % of the causes best describes the discussion, where membrane fouling is the cause (the 20 %) and cleaning is the effect (the 80 %).

Fouling in membrane filtration is problematic but inevitable as it occurs with the retention of contaminants that accumulate on the membrane surface. The causes of fouling are often specific, depending upon feed water constituents, the membrane, and the operating regime. Cleaning protocols are typically recommended by the membrane manufacturers with some cleaners being proprietary. We can minimize the rate of fouling, but we cannot eliminate fouling, unless very extensive pretreatment is applied. Types of fouling are presented along with cleaning, physical and chemical conditions that have significant impacts on cleaning efficiency, and compatibility of membrane materials with cleaning agents.

Membrane fouling is a complicated phenomenon and results from numerous causes. In spite of its complexity, electrostatic and hydrophobic/hydrophilic interactions that involve both membrane and fouling materials are recognized to have significant bearing. This is especially for more-difficult-to-clean membrane fouling dominated by natural organic matter (NOM) and microbes. Membrane fouling is referred to the flux decline of a membrane filter caused by the accumulation of certain constituents in the feed on the surface of the membrane or in membrane matrix. Certain fouling materials can be removed hydraulically (backwash or scrubbing); however, most can be removed by chemical means such as clean-in-place (CIP) or chemical cleaning.

The technique of investigating a fouled membrane – “membrane autopsy” – identifies the cause of poor membrane performance and hence gives the opportunity to rectify or mitigate the problem and improve future plant design.

Membrane Fouling and Chemical Cleaning

Chemical cleaning is an integral part of membrane process operation that has a marked effect on the performance and economics of the process. A decline in RO membrane performance can be caused by fouling (organic and inorganic fouling and biofouling), operational mishaps, and

membrane element quality. The behavior and frequency of RO system fouling are affected by feed water source and quality, pretreatment requirements, pretreatment chemicals, and system design and operation. During normal operation over a period of time, RO membrane elements are subject to fouling by suspended or sparingly soluble materials in the feed water. According to the type of foulants, five categories of membrane fouling are presented.

- Inorganic fouling/scaling
- Particle/colloid fouling
- Biological fouling (bacterial bioslime, algae, mold, or fungi)
- Organic fouling
- Sulfate scale of calcium, barium, or strontium

Generally RO membrane suppliers recommend membrane cleaning when:

- Normalized permeate flow declines by 10 %
- Pressure drop declines by 10 %
- Normalized salt passage increases by 10 %

Well-designed, well-operated RO systems are usually cleaned one to four times per year. Irreversible membrane element performance decline such as membrane compaction and intrusion contributes to the 0.7 flow factor. Based on this permeate flow profile, the system's stabilized performance is a flow factor of 0.7. Cleaning criteria should be based on actual stabilized membrane element performance. The typical cleaning criteria (10 % normalized permeate flow decline or 0.9 flow factor) are not applicable, because true membrane element performance is a permeate flow factor of 0.7. Cleaning performed at a 0.7 flow factor has no effect but increases the OPEX (operating expenses).

Therefore, RO system cleaning criteria must be customized to actual stabilized element performance. The criteria can be customized to site conditions. For instance, calcium carbonate is a foulant that can be easily and effectively removed with a hydrochloric acid solution at pH 2. For sites with low energy costs, cleaning may be carried out when the normalized permeate flow decline is 20 %.

For difficult-to-remove foulants – silicates and organics – cleaning should be performed when the normalized permeate flow decline is 10–15 %. In many cases, commercial membrane cleaners are required but they increase OPEX.

Inorganic Fouling/Scaling

Inorganic fouling or scaling is caused by the accumulation of inorganic precipitates such as metal hydroxides and “scales” on membrane surface or within pore structure. Precipitates are formed when the concentration of chemical species exceeds their saturation limits. Scaling is a major concern for reverse osmosis (RO) and nanofiltration (NF) membrane processes. RO and NF membranes reject inorganic species. These species, if allowed to build up, form a concentrated layer of concentration polarization. For microfiltration (MF) and ultrafiltration (UF), inorganic fouling due to concentration polarization is much less; however, they can exist due to interactions between ions and foulants (organic polymers) via chemical bonding. Coagulation and oxidation, if not designed or operated properly, might introduce metal hydroxides on membrane surface or within pore structure. Inorganic fouling and scaling can be a significant problem for makeup water of caustic solution used for chemical cleaning.

Particulate/Colloidal Fouling

Accumulation of particulate material (dirt, sand) on the membrane surface – plugging – leads to particulate fouling. Algae, bacteria, and certain natural organic matters fall into this category. However, they are different from inert particles and colloids such as silts and clays. In most cases, particles and colloids do not really foul the membrane because the flux decline is largely reversible by hydraulic cleaning measures such as backwash and air scrubbing.

Microbial/Biological Fouling

Microbial fouling is a result of formation of biofilms on the membrane surface. Once bacteria get attached to the membrane, they start to multiply and produce extracellular polymeric substances (EPS) to form a viscous, slimy, hydrated

gel. The severity of microbial fouling is intrinsically related to the quality of feed water like environmental conditions for microbial growth, availability of nutrients, and abundance of microbes. Organic-based deposits resulting from bacterial slimes, fungi, molds, etc. can be difficult to remove, if the feed is plugged. Plugging of the feed makes it difficult to introduce and distribute the cleaning solutions. To inhibit additional growth, it is important to clean and sanitize not only the RO system but also the pretreatment, piping, dead legs.

Bacteria present a significant fouling problem in most of the RO plants. As they grow and multiply, they normally produce biofilm, organic films of lipopolysaccharides, to encase and protect the bacteria. These biofilms cover the membrane surface resulting in fouling.

Chemical Cleaning of Membranes, Fig. 1 Fouled RO membrane

Figure 1 is a photograph of fouled reverse osmosis membranes. Deposits of silt are composed of suspended particulates of all types that accumulate on the membrane surface. Sources of silt are organic colloids, iron corrosion products, precipitated iron hydroxide, algae, and fine particulate matter. Silt density index (SDI) testing is a widely accepted method for estimating the rate at which colloidal and particle fouling will occur in water purification systems, especially using reverse osmosis (RO) or nanofiltration (NF) membranes.

Shown in Fig. 2 are scanning electron micrographs of the surface of the RO membrane after 4 and 16 days. (A) Rod-shaped gels embedded in an extracellular fibrillar material structure (square 1). Compact aggregates are visible on top of this biofilm (square 2). The RO membrane surface is visible at the bottom (under the biofilm layer) as a rough-appearing texture. (B) Typical microcolony formed on the surface of the membrane after 16 days (Fig. 3).

Shown above are series of photographs of fouled reverse osmosis membranes (A) and their feed-side spacers (B). The membranes and spacers were removed from the flow cells after 4 (column 4 d), 8 (column 8 d), 16 (column 16 d), and 32 (column 32 d) days of operation. The direction of the feed water flow along the length of each flow cell was from left to right.

Organic Fouling

Organic fouling is significant in membrane filtration with source water containing relatively high natural organic matters (NOM). Surface

Organic	—	+	—	++

—No effect or negative effects

+Some positive effects

++Always positive effect

^aIn conjunction with feed chlorination

water (lake, river) typically contains higher NOM than groundwaters, with exceptions. For source water high in NOM, organic fouling is the most significant factor in flux decline. NOM typically contains about 50 % humic substances. Some organic molecules (oils, greases, humic/fulvic acids, surfactants), occurring either naturally or synthetic, coat and plug the membrane pores.

The effects of various operating strategies against different types of fouling are summarized in Table 1. As indicated, chemical cleaning is the most effective strategy for all types of membrane fouling.

Chemical Cleaning of Silica Fouling

Chemicals for silica fouling control can be divided into three categories:

- Chemicals for silica inhibition
- Chemicals for silica dispersion (Neofotistou and Demadis 2004)
- Chemicals for silica scale removal from membrane surfaces

Silica inhibitors can retard the polymerization of silica, which exceeded its solubility, i.e., phosphonate-based chemicals. Dispersants can work by placing a surface charge on the polymerized silica and cause repulsion and dispersion of these polymerized structures into water phase (Dudley and Baker 1999).

Polymerization of dissolved silica (i.e., supersaturation and catalyzed by hardness) can be difficult to remove. This type of silica fouling is different from colloidal and particulate silica, which may be associated with either metal hydroxides or organic matter. It might be difficult to remove polymerized silica by typical

chemical cleaning process. However, polymerized silica scales removed with a high pH cleaning solution (pH of 10–11) were reported. Caustic (sodium hydroxide) at maximum pH allowed by the membrane manufacturer will remove polymerized silica scales but it will take many hours to remove a silica scale. Colloidal silica and particulate silica coating, not associated with either metal hydroxides or organic matter, can be removed from membrane surface by physical flushing.

MF and UF membranes can be of organic polymers or inorganic materials, whereas NF and RO membranes are all organic polymers only.

Membrane Cleaning Chemicals

Selection and Use of Cleaning Chemicals

The first time cleaning is performed, it is recommended to contact the manufacturer of the equipment, the RO element manufacturer, and service supplier. The cleaning chemicals can be generic or proprietary.

It is not unusual to use a number of different cleaning chemicals in a specific sequence to achieve optimum cleaning. A high pH cleaning is used to remove foulants like mineral scale or metal hydroxides/oxides. The order of high and low pH cleaning solution could be reversed or only one solution is required under the situation. Detergents are added to aid in the removal of heavy biological and organic matter, while other foulants need a chelating agent like EDTA for the removal of colloidal material, organic and biological material, and sulfate scale. An improper selection of cleaning chemical or the protocol thereof can make the entire cleaning exercise worse.

Iron deposits and scaling require a simple low pH cleaning. For most complex fouling, the sequence below may be followed:

- Flushing with permeate and with nonoxidizing biocide at the end of flushing
- High pH CIP (clean-in-place) with temperature versus pH
- Flushing with permeate till pH on the brine side <8.5

Chemical Cleaning of Membranes, Table 2 Categories of membrane cleaning chemicals

Category	Functions	Typical chemicals
Caustic	Hydrolysis, solubilization	NaOH
Oxidants/disinfectants	Oxidation, disinfection	NaOCl, H ₂ O ₂ , peroxyacetic acid
Acids	Solubilization	Citric acid, nitric acid
Chelating agents	Chelation	Citric acid, EDTA
Surfactants	Emulsifying, dispersion, surface conditioning	Surfactants, detergents (SDS, sodium dodecyl sulfate)

- Low pH CIP (clean-in-place)
- Acid flushing with permeate and nonoxidizing biocide

Once the cause of membrane fouling is identified, various cleaning chemicals can be used to remove foulants from the membrane and to restore the membrane flux. Chemicals commonly used for cleaning MF and UF membranes in water industry fall into five categories, as shown in Table 2.

Caustic

Caustic is used to clean membranes fouled by organic and microbial foulants. The function of caustic is twofold: (1) hydrolysis and (2) solubilization. There are a number of organic materials including polysaccharides, and proteins that can be hydrolyzed by caustic. Cellulose-based membranes based on polysaccharides hydrolyze; hence, such membranes are to be used in a limited pH range. This is due to the hydrolysis of cellulose – a simple polysaccharide – consisting of thousands of glucose linked by 1,4- β -glucoside bonds. Fats and oils also react with caustic through saponification, generating water-soluble soap micelles.

An important function of caustic is to increase negative charges of humic substances. Hence, they are easier to be removed from membranes. Humic substances contain functional groups that are organic acids. Their acidity ranges from pK_a (negative logarithm of the dissociation constant)

of 1.2 (oxalic) to 13 (phenol), with an average pK_a of 4.2 (Thurman 1985). During caustic cleaning, pH of cleaning solution can be as high as 13.

Acids and Chelating

Acids are used primarily for removing scales and metal dioxides from fouling layers. When membrane is fouled by iron oxides, citric acid is quite effective because it not only dissolves iron oxide precipitates but also forms complex with iron. The removal of divalent cations by either acids or chelating reagent such as EDTA improves the cleaning of membranes fouled by organic foulants.

Surfactants

Surfactants are compounds that have both hydrophilic and hydrophobic structures. They can form micelles with fat, oil, and proteins in water and help to clean the membranes fouled by these materials. One interesting but less clear aspect is how surfactants affect membrane fouling dominated by NOM (natural organic matter). As the surfactant is nonionic, the interaction between the membrane and the surfactant is dominated by hydrophilic and hydrophobic reaction. Since the membrane is hydrophobic, hydrophilic tail of the surfactant is preferably adhered to the membrane surface and hydrophilic head is orientated toward aquatic phase. Soaking in surfactant has been used as a method for surface modification to improve hydrophilicity or wettability of certain membranes.

Operating Parameters Affecting Cleaning Efficiency During Chemical Cleaning

Because membrane cleaning is essentially conducted through chemical reactions between cleaning chemicals and fouling materials, factors that affect the mass transfer and chemical reactions such as concentration, temperature, length of cleaning period, and hydrodynamic conditions affect the efficiency of cleaning.

When selecting cleaning conditions, ensure the compatibility of cleaning chemicals with membrane media and filters and systems. Chemical

compatibility of membrane and filter components limits the type and the maximum allowable concentration of a chemical to be used during cleaning.

Concentration of cleaning chemicals can affect both the equilibrium and the rate of reaction. The concentration profile of cleaning chemicals within the fouling layer is a function of the concentration of cleaning chemicals in the bulk liquid phase. Therefore, the concentration of cleaning chemicals not only need to maintain the reasonable reaction rate (kinetics need) but also need to overcome mass transfer barrier imposed by the fouling layer. In practice, the concentrations of cleaning chemicals are usually high enough to satisfy the kinetic need. It is the mass transfer that sets the lower boundary for the concentration of cleaning chemicals.

Temperature can affect membrane cleaning by:

- Changing the equilibrium of a chemical reaction
- Changing the reaction kinetics
- Changing the solubility of fouling materials and/or reaction products during the cleaning

From mass transfer point of view, dynamic cleaning involving circulating cleaning solutions through the system can be more effective than simply static cleaning such as soaking.

RO Membrane Element Cleaning and Flushing Procedures

The RO membrane elements can be cleaned in place in the pressure tubes by recirculating the cleaning solution across the high-pressure side of the membrane at low pressure and high flow. A cleaning unit is needed to do this. RO cleaning procedures may vary depending on the situation. The time required to clean a stage can range from 4 to 8 h.

A general procedure for cleaning the RO membrane elements is:

- Perform a low-pressure flush at 60 psi (4 bar) by pumping clean water from the cleaning tank through the pressure tubes to drain for several minutes. Flush water should be clean water of

RO permeate or DI (deionized) quality water and be free of hardness, transition metals, and chlorine.

- Mix a fresh batch of the selected cleaning solution in the cleaning tank. The dilution water should be clean water of RO permeate or DI quality and free of hardness, transition metals, and chlorine.
- Circulate the cleaning solution through the pressure tubes for about 1 h or as required. At the start, send the displaced water to drain so you do not dilute the cleaning chemical and then divert up to 20 % of the most highly fouled cleaning solution to drain before returning the cleaning solution back to the RO cleaning tank. For the first 5 min, slowly throttle the flow rate to one third of the maximum design flow rate. This is to minimize the potential plugging of the feed path with a large amount of dislodged foulant. For the second 5 min, increase the flow rate to two third of the maximum design flow rate and then increase the flow to two third of the maximum design flow.
- An optional soak and recirculation sequence can be used, if necessary. The soak time can be from 1 to 8 h depending on the manufacturer's recommendations but not to exceed maximum pH and temperature limits for specific elements.
- Upon completion of the chemical cleaning steps, a low-pressure cleaning rinse with clean water (RO permeate or DI quality and free of hardness, transition metals, and chlorine) is required to remove all traces of chemical from the cleaning skid and the RO skid. Drain and flush the cleaning tank; then completely refill the cleaning tank with clean water for the cleaning rinse. Rinse the pressure tubes by pumping all of the rinse water from the cleaning tank through the pressure tubes to drain.
- Once the RO system is fully rinsed of cleaning chemical with clean water from the cleaning tank, a final low-pressure cleanup flush can be performed with pretreated feed. The permeate line should be open to drain. Feed pressure should be less than 60 psi (4 bar). This final flush continues till the flush water is clean and is free of any foam or residues. This flush goes

for 15–60 min. A conductivity meter can be used to test for removal of cleaning chemicals, such that the flush water to drain is within 10–20 % of the feed conductivity. A pH meter can also be used to compare the flush water to drain to the feed pH.

- Once all the stages of a train are cleaned, and the chemicals flushed out, the RO plant can be restarted and placed into a service rinse. The RO permeate should be diverted to drain until it meets the required quality of the process. It normally takes few hours to few days for the RO permeate quality to stabilize, especially after high pH cleanings.

Conclusion

As the water treatment industry grows at a remarkable pace, the ability to treat aggressive surface and waste waters that are notorious for having high organics, colloids, and biological fouling potential continues to be challenging.

Using a generic or commercial alkaline cleaning chemical significantly affects OPEX, while the payback primarily depends on the chemicals used. Cleaning to reduce a facility OPEX depends on water temperature, energy costs, and chemical costs. Establish a cleaning strategy that is most effective and well tested; analyze the foulants followed by an autopsy protocol. Selection of an appropriate pretreatment with good operation and maintenance practices will lead to cost-effective cleaning regime. The cleaning efficiency depends on the type of cleaning agent and its concentration. The net effect is that the efficiency increases with increasing chemical concentration. Operating parameters such as cross-flow velocity, turbulence in the vicinity of membrane surface, temperature, pH, and duration of cleaning affect the cleaning process. Analyze the right cleaning strategy on a case-by-case basis. It is recommended that the MSDS (Material Safety Data Sheet) of the cleaning chemicals be procured from the chemical supplier and knowledge be applied in the handling and storage of the chemicals.

Chemical Industry and Membrane Operations

Paola Bernardo

Institute on Membrane Technology, National Research Council, ITM-CNR, Rende, Italy

Chemical industry is a complex of processes, involved in the manufacture of chemicals and their derivatives. Generally, a production cycle comprises the conversion of raw materials and the product recovery and purification. Separation processes are among the most energy-intensive stages. Membrane technology is widely accepted and well established in the chemical industry, allowing to decrease equipment size, raw

materials, and energy utilization, as well as waste generation, in the process intensification logic (Stankiewicz and Moulijn 2000). Membrane processes have several advantages than conventional separation techniques (e.g., distillation, extraction, absorption, and adsorption), including modularity and compactness, operational flexibility, no need for energy-intensive phase changes, or potentially expensive adsorbents and/or difficult-to-handle solvents.

The separation of hydrogen from nitrogen in ammonia plants was the first large commercial application of membrane-based gas separation (Bernardo et al. 2009). Compact and modular membrane modules, mainly in the form of hollow fibers, are widely used for nitrogen production to inert fuel tanks, also aboard aircrafts, and for blanketing chemical, methanol, and liquefied gas shipments to enrich oxygen for medical uses, for hydrogen recovery and purification, for air and gas dehydration, and for ratio adjustment of gas mixtures.

Membranes represent a valid alternative to chemical treatment in the wastewater treatment, producing a cleaner and more reliable effluent for discharge or recycle, reducing, at the same time, chemical, analytical, and labor costs. Membrane technology has a significant role in the production of different grades of process water and in a recycle/reuse logic. Depending on the nature and variability of the feed supply, ultrafiltration or microfiltration membranes can effectively perform the pretreatment for reverse osmosis, removing bacteria and solid particles (Lefebvre and Moletta 2006). Membrane bioreactors, by combining the traditional biological degradation with a solid–liquid separation by means of low-pressure membrane filtration (ultrafiltration or microfiltration), are appropriate solutions in the industrial wastewater treatment to reduce plant footprint and operating costs (Marrot et al. 2004).

Filtration membranes are variously used for concentration and/or recovery purposes in different industrial cycles: in the production of pigments, surfactants, electronics, textiles, pulp, and paper, in the industrial laundering, and in the chemical and mineral processing. Acid- and

base-stable membranes, based on ceramic materials, are suited for the concentration and demineralization of dyes in acids; the decolorization, clarification, or demineralization of spent acid and caustic solutions for recycle; and the concentration, desalination, and softening of in-process and waste streams and for COD and BOD reduction in waste streams such as pulp and paper waste effluents.

Pervaporation allows organic dewatering, especially from ethanol and isopropanol (Van der Bruggen 2009). The development of solvent-stable membranes has permitted the progress of organic solvent nanofiltration which is applied for nonthermal solvent recovery; in situ recycling of organic solvents; purification, and concentration of intermediates; product upgrading; and continuous recovery of homogeneous catalysts (White 2006). Moreover, significant progresses have been done in the recent years in developing other unit operations such as membrane reactors (Shirasaki et al. 2009) and membrane contactors (Klaassen et al. 2005), covering all the chemical engineering unit operations. Membrane contactors, accepted into the beverage industry for carbonation, deaeration, and nitrogenation, are effectively used in degassing applications and corrosion control.

The range of application of the membrane technology could be extended with the availability of new membrane materials able to withstand more demanding process conditions of temperature, pressure, and aggressive conditions. Other interesting options are related to hybrid systems in which membrane technology is combined with another separation process, improving overall process efficiency and offering the opportunity of developing, reengineering, or retrofitting chemical processes (Koltuniewicz 2010).

Chemical Looping

Fausto Gallucci

Chemical Process Intensification, Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands

Among different strategies for CO₂ capture, a new emergent technology is focusing the attention: chemical-looping combustion (CLC). This novel concept could reduce up to 50 % of the costs of CO₂ capture in regard to current technologies. For that reason, the IPCC remarked CLC as one of the cheapest technologies for CO₂ capture. It was in 1987 when Ishida et al. introduced by the first time the term chemical-looping combustion for power generation and later as a powerful technology for CO₂ capture (Ishida and Jin 1994; Ishida et al. 1987). The technology is referred to as a

cycling system where a solid with high oxygen capacity called oxygen carrier transfers the oxygen needed to convert the fuel. By this way, CO_2 produced by the combustion of the fuel is not diluted in the N_2 (from the air) because direct contact between fuel and air is avoided. Hence a CO_2 -rich stream is produced at the exit point of the reactor. It implies lower energy requirements for CO_2 capture than other strategies where CO_2 and N_2 are mixed. The main drawback of this technology is the lack of maturity, and for that reason the interest in the system has increased during the last years as can be discussed in the recent review by Adánez et al. (2012). More than 700 different oxygen carriers have been already tested, and the performance of the concept has been tested in different CLC units in the size range 0.3–120 kW_{th}.

Chemical looping systems have not been exclusively focused on fuel combustion for power generation but also for fuel reforming (mainly methane) for syngas production. This concept is called chemical-looping reforming (CLR). The CLR occurs if at the fuel reactor the CH_4 is fed with steam and with a lower amount of oxygen (compared to the CLC) contained in the oxygen carriers. In this way, the fuel conversion gives a reformed syngas with high H_2 concentration. The system behaves like an autothermal reformer, and the heat for the endothermic reaction is directly supplied by burning part of the methane. It has been operated for short times in lab-scale systems at moderate pressures (Rydén and Lyngfelt 2006; Rydén et al. 2008a, b). In total around 100 h operation of CLR have been demonstrated worldwide (Adanez et al. 2012). The main research in literature has been focused on oxygen carrier studies for reforming of natural gas. The typical reactor scheme of CLR is similar to the well-known CLC but differs in the desired product, which in CLC is heat and in CLR is syngas. Recently, Gallucci et al. proposed the application of a chemical-looping reforming where the fuel reactor is replaced by a membrane-assisted fluidized bed reactor. This new concept named membrane-assisted chemical-looping reforming (MA-CLR) gives many advantages over the previous concepts especially because a

much higher hydrogen recovery can be obtained at lower temperatures.

Chemical Membrane Reactors

Lidietta Giorno

Institute on Membrane Technology, National Research Council, ITM-CNR, Rende, Italy

Chemical membrane reactors are membrane reactors using chemical catalysts, mainly of inorganic origin.

Both dense and porous membranes are used in membrane reactors. Dense membranes are made of polymers, metals and their alloys, and solid oxides. Dense metal membranes mostly consist of Pd, Pt, Ru, Rh, Ag, and their alloys. Pd membranes and its alloys are used for dehydrogenation reaction. They have high selectivity toward hydrogen, while Ag membranes are selective toward oxygen.

Chemical Membrane Reactors, Fig. 1 Packed bed membrane reactor with the membrane formed of a mesoporous film catalytically active and a porous inert support layer

Solid oxides (ZrO_2 , BiO_3 , Y_2O_3) and solutions of mixed solid oxides (such as perovskite-type oxides) have been used as dense membranes selective for oxygen or hydrogen. They are used in catalytic membrane reactors for partial and total oxidation reactions.

Mesoporous membranes made of alumina, titania, and zirconia are also used to prepare membrane reactors. Microporous membranes made of zeolites have been also prepared.

As a general example of modeling of chemical membrane reactors, here is reported the case of a packed bed membrane reactor with the membrane formed of a mesoporous film catalytically active and a porous support layer inert (Fig. 1). The tube and shell sides are occupied by packed bed catalysts.

The reaction occurs in gas phase. The gas transport through the mesoporous membrane layer takes place by Knudsen diffusion. Surface flow and diffusion through the porous region are considered to be negligible. The reaction could take place inside the catalytically active membrane and/or in the packed beds placed in the tube- and/or shell-side compartments. Based on these assumptions, the model equations in cylindrical coordinates and the corresponding boundary conditions for each region showed in the Fig. 1 are described as follows:

In the tube side (*region a*):

$$V_f \frac{\partial C_i^a}{\partial z} = D_i^a \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial C_i^a}{\partial r} \right) - \rho_b \alpha_i v^a \quad (1)$$

with $0 \leq r \leq r_a$ and $0 \leq z \leq L$.

V_f is the superficial fluid velocity (m s^{-1}); C_i^a is the concentration of species i in region 1; D_i^a is the effective radial diffusivity through the packed bed in the tube; ρ_b is the reactor bed density; α_i is the stoichiometric coefficient; and v^a is the apparent reaction rate ($\text{mol kg}^{-1} \text{s}^{-1}$).

In the reactive membrane (*region b*):

$$D_i^b \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial C_i^b}{\partial r} \right) = \rho_m \alpha_i v^b \quad (2)$$

$$r_i \leq r \leq r_m$$

ρ_m is the membrane density; D_i^b is the membrane diffusivity; and v^b is the observed reaction rate.

In the macroporous support (*region c*):

$$D_i^c \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial C_i^c}{\partial r} \right) = 0 \quad (3)$$

$$r_m \leq r \leq r_s$$

In the shell region (*region d*):

$$U_d \frac{\partial C_i^d}{\partial z} = D_i^d \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial C_i^d}{\partial r} \right) - \rho_b \alpha_i v^d \quad (4)$$

$$r_s \leq r \leq r_e$$

$$0 \leq z \leq L$$

Catalytic Membrane Reactors with Nonselective Membrane (CNMR)

In these types of membrane reactors, the membrane may act as a contactor device (catalytic) or may serve to distribute reactants in an uniform way (inert). In modeling such reactors, Knudsen diffusion as well as molecular diffusion and convective transport may occur. The dusty gas model of transport is typically utilized. Membrane reactors using mesoporous membranes and operating under a transmembrane pressure gradient may also use this model. For such reactors, an isothermal model that consists of mass balance equations in every membrane compartment can be used. For example, for compartments where reaction occurs, the mass balance is

$$\nabla J_i = V_{r_i} \quad (5)$$

while in nonreactive regions

$$\nabla J_i = 0 \quad (6)$$

where J_i is the flux of species i and V_{r_i} is the corresponding reaction rate. According to the dusty gas model, J_i is described as:

$$\sum_{j=1, j \neq i}^n \frac{X_i J_i - X_j J_j}{PD_{ij}} - \frac{J_i}{PD_{ik}} = \frac{1}{RT} \nabla x_i + \frac{J_i}{PRT} \left(\frac{B_0 P}{\mu D_{ik}} + 1 \right) \nabla P \quad (i = 1 \dots n) \quad (7)$$

where D_{ij} is the effective binary diffusion coefficient of components i and j (already includes the

porosity and the tortuosity of the membrane), D_{ik} is the corresponding effective Knudsen diffusion coefficient, and x is the molar fraction. B_0 corresponds to the permeability coefficient for convective flow in m^2 , and μ is the viscosity in $\text{N}\cdot\text{s}/\text{m}^2$. D_{ij} , D_{ik} , and B_0 are empirical parameters, which depend on the structure of the porous membrane.

Chemical Pretreatment

Graeme K. Pearce

Membrane Consultancy Associates Limited,
Reading, RG8 7EJ, UK

Definitions

The term *chemical pretreatment* refers to the use of coagulant chemicals to form flocculant (floc) particles in a water-based feed stream to enhance contaminant removal.

Objectives

The purpose of chemical pretreatment is to entrap particulates and to some extent dissolved contaminants, for subsequent removal by gravity settlement or flotation, or by removal in a physical filtration step (see *granular media pretreatment* and *physical pretreatment*).

Process Principles and Mechanisms

Water treatment relies on settlement to remove large particles, followed by filtration to remove finer ones. A wide variety of particulate and dissolved contaminants can be found in water and wastewater sources (Parsons and Jefferson, 2005). Larger particles are held in suspension in a flowing stream and settle rapidly if the feed is stored. As particle size becomes finer, settling velocities reduce sharply and below a size of 10 μm , rates become so low that it is not practical

to remove these contaminants by settlement processes alone, as illustrated in Table 1.

In a typical water source, fine particles are held in suspension in a stable dispersed state. There are forces of gravity attraction between particles, but for small particles, the forces are not sufficient to lead to natural agglomeration, which would aid their removal by settlement. Indeed, forces of electrostatic repulsion tend to prevent particles coming together, particularly for submicron sizes, and the random forces of Brownian motion contribute to maintaining colloids and macromolecules in suspension.

Colloids can give rise to turbidity and affect other aesthetic water quality parameters such as color and so need to be removed in the water

treatment process. If derived from organic matter such as algae, they may cause fouling in downstream processes such as RO, or could be responsible for toxic residuals in treated water.

Coagulation is the process used to destabilize the dispersed suspended matter as illustrated in Fig. 1. The colloids tend to have a negative charge at the surface which generates a significant repulsion between particles. The coagulant neutralizes the surface charge and overcomes the repulsive forces. In the figure, trivalent Al^{3+} ions are used to fulfil this role.

Hydrophilic molecules and ionic species have strong bonds of hydration to water molecules which assist their stable dissolution in water. In contrast, hydrophobic molecules do not bond to water and are easy to separate from a bulk water medium. However, naturally occurring dissolved organic molecules and colloids are often amphiphilic in nature having a portion of the molecule which is hydrophilic (water loving) and a portion which is oleophilic (oil loving). The oleophilic portion is likely to also be hydrophobic (water hating), giving rise to the synonymous term amphipathic.

Common contaminants in surface water include humic and fulvic acids which are responsible for color and can give rise to disinfection

Chemical Pretreatment, Table 1 Settling velocities for common particles and colloids

Particle diameter mm	Type	Settling velocity
10	Pebble	0.73 m/s
1	Coarse sand	0.23 m/s
0.1	Fine sand	0.6 m/min
0.01 (10 μ m)	Silt	8.6 m/day
0.0001 (0.1 μ m)	Large colloids	0.3 m/year
0.000001 (1 nm)	Small colloids	3 m/million year

Chemical Pretreatment, Fig. 1 Colloid destabilization

Chemical Pretreatment, Fig. 2 Floc particle

by-product residuals after chlorination. These macromolecules are examples of colloids with strong amphiphilic character. Coagulants assist in the removal of these colloids by displacing hydration water from the hydrophilic portion of the molecule and associating with the hydrophobic portion through charge attraction. The Al^{3+} sites then attract hydration water and the partly neutralized particle agglomerates with other coagulated particles to create the rapid buildup of a floc particle as shown in Fig. 2.

The initial dispersion phase takes between 10 and 120 s. Once the coagulation process has been initiated, the process of flocculation can then proceed, i.e., the agglomeration of the destabilized particles. The growth phase can take up to 40 min, though in commercial processes, it is normal to use considerably less time than this. The initial seed for the floc to form is normally a small particle or colloid, but as it grows, dissolved organics become associated with the floc due to their charge or surface character and can therefore be removed from the bulk liquid phase. Coagulation can therefore be used to reduce total suspended solids and turbidity, and to some extent dissolved organics, thereby providing a significant impact for the improvement of water quality.

Coagulant Chemical Categories

Dosing chemicals fall into three categories:

- Inorganic coagulants
- Inorganic polymeric coagulants
- Organic polymeric coagulants

The most common inorganic coagulants used in water treatment are Al^{3+} salts added as aluminum chloride or aluminum sulfate (alum) and Fe^{3+} salts added as ferric chloride or ferric sulphate (Bache and Gregory, 2007). The coagulation reaction of alum is shown below:

The optimum pH for the hydrolysis reaction shown is 5.5–6.5. However, note that the reaction conditions are only satisfied for feed water with a significant level of bicarbonate alkalinity. According to the equation above, 1 mol of alum consumes 6 mol of bicarbonate, so in a soft, low alkalinity water, there may not be sufficient naturally occurring calcium bicarbonate to support the required reaction. In this case, the reaction generates sulfuric acid, causing the pH to drop sharply, as shown in the following equation. Note that lime addition would be required to neutralize:

Ferric chloride consumes half the molar concentration of bicarbonate in its hydrolysis reaction since there is only one ion of Fe^{3+} for each ferric chloride molecule, whereas the sulfate in alum is divalent. The hydrolysis equation is:

The optimum pH for Fe^{3+} is 4.5–5.5, but there is a wider range of pH that can be used in different circumstances of 4–9. Thus, Fe^{3+} is less pH sensitive than Al^{3+} and normally provides better turbidity, color, and natural organic matter (NOM) removal at a given molar concentration. As with Al^{3+} , acidity will be created if the bicarbonate concentration is insufficient, requiring lime addition.

Due to the higher density of floc particles with Fe^{3+} , the sludge has better settleability and is often preferred for clarification applications. Fe^{3+} produces a higher sludge mass. Al^{3+} can struggle in cold water conditions, but is often preferred for dissolved air flotation, since this process relies on the low density of the floc particle. In some countries Fe^{3+} is preferred to Al^{3+} for health reasons.

The basic coagulation chemistry of both inorganic and organic polymeric coagulants is similar to the straightforward inorganic coagulants, but the pH tolerance may be wider and the effectiveness of the coagulation and subsequent flocculation reactions may be improved. The most common coagulant in the second category is polymeric aluminum chloride (PACl), which is used to overcome problems associated with Al. PACl has better binding with clays, etc. due to higher charge density. In general water treatment, poly-aluminum coagulant hybrids can be used, but these are not often encountered in UF pretreatment, though aluminum chlorohydrate (ACH) is found to be effective. Coagulants with a higher charge density can be more effective at neutralizing the negative charge of colloids and will tend to initiate agglomeration more rapidly, growing stronger floc particles.

The third category of coagulant is the organic polymeric category. The most common example in this group is the cationic polymeric coagulant PDADMAC which has a high charge density giving good removal of clays and organics. It can be typically used at 10 % of the inorganic coagulant concentration and has low sludge yield. Some cationics can bind to membrane surfaces, so UF users are very cautious and the often chemically related category of floc aid is also used with great care due to the risk of attachment. Fortunately, floc aids are not normally needed in membrane pretreatment.

In summary, both Fe and Al compounds are widely used in chemical pretreatment, but Fe is more often selected for use in membrane pretreatment, utilizing low dosing concentrations. PACl is sometimes successfully employed, but high-performance organic coagulants are less often used due to cost and concerns about fouling. The low coagulant concentrations provide a key

advantage in reducing sludge disposal costs, and this is likely to become an even more important factor in the future, outweighing chemical purchase cost considerations in some circumstances.

Coagulation Conditions

Establishing the correct conditions for coagulation first requires a selection of the correct coagulant from the options described in the previous section. The appropriate coagulant concentration and pH will then need to be determined, as well as the correct physical conditions. These requirements may vary depending on the process selected for the formation and removal of the floc. Choosing the right coagulant often requires a review of comparable applications in terms of feed water type and temperature, with similar process requirements. If there is no direct comparison, several alternatives might need to be explored.

The next step is to determine the best conditions for the coagulant chosen. This is normally carried out by conducting jar tests. In these tests, a number of beakers are set out with the feed and coagulant at different concentrations and pH conditions. A typical jar test set up is shown in Fig. 3.

As well as varying coagulant concentration, another series of tests may be carried out at a promising concentration with a variation of the pH from say 5.0–7.5 in increments of 0.5 of a pH unit between jars. The jars are mixed in a consistent way with the addition of the coagulant and the time noted for floc formation. A typical procedure would use 1 min of rapid mixing at 100–150 rpm to ensure quick dispersion of the coagulant throughout the mixture, followed by a period of 14 min at a slow mixing speed of say 25–30 rpm. The emergence of floc is noted, and the turbidity of the supernatant is measured once stirring has stopped. It is also instructive to observe floc settleability. A plot of residual turbidity against pH as shown in Fig. 4 will indicate the optimum coagulation condition, which in the case of the graph above is 6.3

Chemical Pretreatment,

Fig. 3 Jar test showing different Al^{3+} concentrations with a 15 min contact time

**Chemical Pretreatment,**

Fig. 4 Residual turbidity versus pH

**Process and Implementation**

In water and wastewater treatment, coagulation is often required to improve the removal performance of conventional processes such as sand filters. For a conventional process flow scheme, the coagulation step is normally conducted prior to filtration using a clarifier or dissolved air flotation (DAF) unit. Membrane processes are less reliant on coagulation, but they are still used quite frequently. Wastewater reuse applications always use coagulant and it is used in over half of surface water capacity and also quite frequently in seawater treatment. However, the use of coagulants in groundwater treatment is unusual.

The key issue for coagulant addition is to ensure a rapid dispersion of the dosed chemical after the injection point so that it is well dispersed through the bulk liquid, followed by an opportunity for the floc to grow in relatively low shear conditions. Rapid dispersion requires a good mixing stage which can be achieved by a dosing injection point immediately prior to a pump or strainer, thereby using the pump impeller or strainer media to achieve the mixing. Alternatively an in-line mixer can be used in the pipe just after the injection point, or if in a tank, a baffled flowpath is created. It is important that process shear is applied immediately after injection, i.e., within the first few seconds. Once the

floc has formed and starts to grow, high shear operations may break up the floc, and it could be difficult to get the floc to regrow. This can cause high turbidity and fouling of downstream unit operations.

In general, coagulation in membrane pretreatment flow schemes may be considered for the following reasons:

- Improve general feed quality to increase UF/MF flux
- Ameliorate feed quality excursions such as turbidity spikes and, in the case of seawater pretreatment, algal bloom, and red tide events
- Reduce dissolved organic concentration to lessen biofouling

Operational Issues

It is important for a coagulant to produce a floc which will be effectively removed in downstream process operation. If the removal is to be achieved by settlement in a clarifier, the floc needs to be large, dense, and fairly robust. For filtration through a granular media filter, the floc needs to be large and robust. Sometimes, a polymeric coagulant or floc aid could be used as a floc strengthener or enlarger to assist growth of the floc to improve removal by settlement or filtration, and make it less likely that the floc will be broken up through process shear. If it is to be removed in a dissolved air flotation unit, the floc needs to be low in density. If the floc is formed by direct in-line injection just prior to a membrane filtration stage, it is likely that a microfloc would be sufficient.

Although clarifiers or DAF are sometimes used upstream of the membrane in some pretreatment applications, a significant proportion of membrane systems use in-line dosing at low coagulant dose with a minimal contact time at 20–30 s. This has provided the opportunity for membrane systems to cut coagulant doses radically from levels of several ppm used for clarification or DAF to 1 ppm or less (as Fe^{3+}) for in-line dosing.

The main concern in the use of coagulants with membrane pretreatment processes is the

danger of coagulant fouling, potentially both of the UF or MF membrane and/or of any downstream RO. This may occur due to overdosing or floc disruption from shear, either as a result of pumping or excessive transmembrane pressure (TMP). In seawater applications, the current trend is to eliminate in-line dosing during good feed quality periods and to use a low and variable dose during periods of poor or variable quality. Different membranes respond differently to coagulants, and so selection of the coagulant procedure is often carried out through pilot trials or comparison with other operations using similar feeds.

Chemical Vapor Deposition

Hiroki Nagasawa and Toshinori Tsuru
Department of Chemical Engineering, Hiroshima University, Higashi-Hiroshima, Japan

Chemical vapor deposition (CVD) is a method for depositing thin films of various materials (Smith 1995). CVD process involves a series of gas phase and surface reactions of volatile precursors, which are induced by, for example, heat, light, and/or plasma-discharge. CVD has been used extensively in a number of industries such as semiconductor, electronics, and optics industries.

CVD techniques have also been utilized in the fabrication of inorganic molecular sieve membranes. Among the types of CVD technique, thermal CVD has been most extensively studied since Gavalas and coworkers first reported successful synthesis of the hydrogen-selective silica membranes in 1989 (Gavalas et al. 1989). There are

Chemical Vapor Deposition,

Fig. 1 Schematic diagram of (a) one-sided and (b) counter-diffusion CVD processes

two types of reaction geometries available for thermal CVD, as shown in Fig. 1: one-sided CVD and counter-diffusion CVD (Nomura et al. 1997; Nakao et al. 2000). For the case of the one-sided CVD, all of the reactants are fed to the same side of the porous substrate, and then, the film-forming reactions occur at the surface of the substrate. On the other hand, for the case of the counter-diffusion CVD, the reactants are fed to the opposite side of the substrate. The reactants diffuse into the porous substrate and the reactions take place at the location where the reactants contact each other. Therefore, the deposition occurs inside the pores and the pore size will be decreased. The deposition continues until the pore size becomes small enough to reduce diffusion of the reactants. As a result, uniform pore size can be obtained by using the counter-diffusion CVD.

The hydrogen-selective silica membranes reported by Gavallas et al. were prepared by depositing a dense silica layer on the top of Vycor glass membranes by the oxidation of SH₄ at 450 °C (Gavallas et al. 1989). The obtained membranes were reported to have high H₂/N₂ selectivities as high as 3,000 but low H₂ permeances of 2.1×10^{-8} mol/(m² s Pa) at 450 °C. Until then, a great deal of progress has been made by several research groups. For

example, Gu and Oyama prepared a silica membrane on the substrate with a graded γ -alumina intermediate layer by the thermal decomposition of tetraethoxysilane (TEOS) at 600 °C and reported H₂ permeance of 5.0×10^{-7} mol/(m² s Pa) at 600 °C, with H₂/CH₄ selectivity of 5,900 (Gu and Oyama 2007). Ohta et al. prepared silica membranes on the γ -alumina intermediate layer by using oxidation of tetramethoxysilane (TMOS), phenyltrimethoxysilane (PTMS), or dimethoxydiphenylsilane (DMDPS) at 600 °C and reported that larger pores were formed when the number of phenyl groups on the precursor was increased (Ohta et al. 2008). The DMDPS-derived membrane showed a high H₂ permeance of the order of 10^{-6} mol/(m² s Pa) at 300 °C, with H₂/SF₆ selectivity of 6,800.

Plasma-enhanced CVD (PECVD) is another type of CVD technique utilized for the membrane fabrication. PECVD offers a low processing temperature compared with thermal CVD due to the high reactivity of plasma. Several research groups reported the PECVD-derived membranes prepared at room temperature by using several kinds of precursors such as hexamethyldisiloxane (HMDSO) (Roualdes et al. 2002; Tsuru et al. 2011; Nagasawa et al. 2013), hexamethyldisilazane (HMDS)

(Kafrouni et al. 2009), or bis(dimethylamino) dimethylsilane (BDMADMS) (Kafrouni et al. 2010). Typical PECVD-derived membranes showed moderate selectivity (e.g., He/N₂ selectivity of <10 at 25 °C and ~30 at 150 °C) with He permeance of the order of 10⁻⁸–10⁻⁷ mol/(m² s Pa), probably because the PECVD-derived layer remains to have high content of organofunctional groups which make the structure more loose (Roualdes et al. 2002; Tsuru et al. 2011; Nagasawa et al. 2013; Kafrouni et al. 2009, 2010). Selectivity of PECVD-derived membranes can be improved by 2-step PECVD sequence, which involves HMDSO/Ar-PECVD followed by HMDSO/O₂-PECVD (Tsuru et al. 2011; Nagasawa et al. 2013). Moreover, the membrane prepared via 2-step PECVD showed a good thermal stability, although the membrane was fabricated at room temperature. The 2-step PECVD-derived membrane showed high He and H₂ permeances of 5.2 × 10⁻⁷ and 2.4 × 10⁻⁷ mol/(m² s Pa) at 400 °C, respectively, with He/N₂ and H₂/N₂ permeance ratios of 4,200 and 1,900, respectively (Tsuru et al. 2011; Nagasawa et al. 2013).

Chemometrics

Rocco Caliandro

Institute of Crystallography, CNR, Bari, Italy

Chemometrics can be defined as “information aspects of chemistry”, where statistical and mathematical methods are used to produce “good data” and to extract relevant information from measured data (Wold and Sjostrom 1998). The first aim can be achieved by using design of experiments (DoE) to provide a small number of information-rich experiments. Multivariate data analysis and advanced data visualization can be employed for the second purpose. In fact, multivariate projection methods can be used to simplify complex data and thus make the visualization easier. Furthermore they can be used for classification of samples and to predict outcomes.

Theory of DoE and literature with references covering the field of experimental design and optimization can be found in Box et al. 1978; Gabrielsson et al. 2002; Lundstedt et al. 1998; Mandenius and Brundin 2008. Instrumentation developed in the field of process analytical chemistry (PAC) supplies data about the state of a process (Callis et al. 1987). Combination of PAC instrumentation and multivariate analysis provides tools for effective process monitoring

Chemometrics, Fig. 1 X-ray diffraction profiles and calibration plot of a PLS model for quaternary carbamazepine-saccharin mixtures

and control enabling detection of multivariate relationships between different variables such as raw materials, process conditions, and end products.

DoE represents a special case of predictive modeling. The objective of predictive modeling is to determine the relationship between several x-variables (often called independent or explanatory variables) and one or more y-variables (dependent or response variables). This objective can be achieved by means of a regression model, where the observed result, i.e., response (y), is described as a function of the x-variables. Models can be seen as tools to describe reality. Empirical models based on the experimental data can be estimated and used for interpretation and prediction. All models are more or less erroneous, since there are always noise and other irrelevant features in the data. Experimental error is produced by both known and unknown disturbing factors that may confound important effects wholly or partially. This can be reduced and sometimes almost eliminated by using DoE and statistical analysis.

Multivariate data analysis has proven to be a powerful tool when combined with advanced characterization techniques. Apart from regression models, it also uses latent variable methods, such as principal component analysis (PCA) and partial least squares (PLS), for classification and prediction purposes. Measured variables, which describe partially or fully the same property of a

system, provide similar information content. Collinear variables can be combined and described by fewer, so-called factors or latent variables, which describe the underlying structure in the data. In modeling, the prime aim is to separate information from noise and find the crucial patterns in the data. Following the introduction of computers and computerized measurement techniques, latent variable methodology has penetrated nearly all areas where complex systems are measured and modeled, and it is especially powerful when huge amounts of data are produced and systematic approaches are needed to reveal the information in the data.

In the framework of membrane technology, chemometrics can be used for process optimization, which includes quality control of components, and for characterizing the products of the process. For example, in the process of membrane crystallization, chemometrics allows to find the best setting of parameters ruling the process (solvent flux, precipitant and solute concentrations, temperature, geometry, amount of solution), to control the quality of the membranes and plates used, and to characterize the crystals produced. Regression models allow to predict crystallization products given a set of (unexplored) parameter setting. As an example, the X-ray diffraction profiles measured for mixtures formed by polymorph III of carbamazepine, saccharin, and cocrystal carbamazepine-saccharin produced by

membrane crystallization have been processed by PLS, which are able to supply precise quantitative predictions on their concentrations through the calibration plot shown in Fig. 1 (Caliandro et al. 2013).

Chiral Drug Separation by Membranes

Keiji Sakaki

National Institute of Advanced Industrial Science and Technology (AIST), Research Institute for Sustainable Chemistry, Tsukuba, Ibaraki, Japan

An enantiomer is one of two stereoisomers that are mirror images of each other and non-superposable. This feature of an enantiomer is called “chirality.”

Chirality is a very important key word in pharmaceutical industry, because more than half of pharmaceutically active ingredients are chiral (Sekhon 2010). In chiral drugs, one enantiomer shows desirable bioactivity, but the other enantiomer frequently does the less bioactivity or sometimes toxic side effects. Therefore, worldwide

sales of single-enantiomer drugs have been growing (Maier et al. 2001; Li and Haynie 2007).

There are some techniques to prepare single-enantiomer drugs in pharmaceutical industry. One is chemical synthesis using chiral building blocks as starting materials. Another is asymmetric synthesis using enantioselective catalysts like chiral organocatalysts or biocatalysts. Optical resolution of enantiomers in a racemate is another important technique in chiral drug industry. The method of optical resolution can be applied to not only final racemic drugs but also racemic intermediates appeared in preparation steps.

We already have some techniques to separate one enantiomer from the other isomer: preferential crystallization, chiral chromatography, enantioselective extraction, enzymatic kinetic resolution, membrane separation, and so on. Among these techniques, membrane-based method has some advantages such as low energy demand, continuous operation, and easy scale-up. The important factor of membrane-based enantioselective separation is the way how to give the function of chirality recognition to membranes. In a supported liquid membrane, a liquid containing enantioselective carriers is impregnated into a porous support membrane (see the topic “► [Supported liquid membrane for enantioselective separation](#)”). In enantioselective solid membranes, chirality recognition exists in main polymer chain, chiral polymer branch, doped chiral selector, or cavity formed by molecular imprinting (see the topic “► [Enantioselective transport of amino acids by membrane operations](#)”).

Although the industrial application of membrane-based chiral separation has been very few until now, one successful example exists in chiral drug production. Diltiazem is a calcium channel blocker used for hypertension and angina treatment, and a lipase-immobilized membrane reactor was applied to the enantiomeric separation of chiral intermediate of this drug (Lopez and Matson 1997). In the separation process, a biphasic membrane system is used. Figure 1 shows the concept of enantiomeric separation in a biphasic membrane reactor using enzyme immobilized on the membrane surface. The

Chiral Drug Separation by Membranes,

Fig. 1 Concept of enantiomeric separation in a biphasic enzyme membrane reactor

immobilized enzyme on a membrane hydrolyzes preferentially one isomer ester in the organic feed phase, and the produced acid is extracted into the aqueous phase. In this system, reaction and separation occur simultaneously in/on membranes.

Membrane technology has a potential to improve the application of enzymatic reactions to the industrial scale production of chiral drugs. The recent progress of enzymatic membrane reactors was reviewed elsewhere (Rios et al. 2004).

The most important factor for successful optical resolution of enantiomers in a racemate is the design of a chiral selector fitting for the separation, because many drugs have complicated steric structures. One of the measures devised to deal with this problem is the implementation of combinatorial strategies (Maier et al. 2001). Large libraries of potential selectors are generated, and the systems with desirable properties are extracted from the libraries.

Chlorination Process

Zhi Wang

Chemical Engineering Research Center, School of Chemical Engineering and Technology, Tianjin University, Tianjin, China

Chlorination process, in chemistry, is a halogenation reaction using chlorine. Because chlorine is a highly efficient disinfectant, chlorine is widely used in the treatment of water. In this case, the chlorination process is the addition of chlorine or chlorine compound. Aqueous free chlorine solutions contain three species in equilibrium, Cl_2 , HClO , and ClO^- . At present, it is generally accepted that the chlorination is closely related to the major chlorinating species in free chlorine solution and their concentration, both of which depend on the pH of the solution.

For membranes, the chlorination is the reaction of chlorine with membrane materials. The chlorine is widely used as the pretreatment agent during many kinds of membrane process because of their oxidability. However, this oxidizing chlorine can react with membrane, resulting in membrane failure. Usually, the hydrogen atom in the membrane is substituted by the chlorine atom. Many materials used for membrane fabrication contain active hydrogen. One of the most famous ones is polyamide, which is widely used for the fabrication of many kinds of membranes such as reverse osmosis membrane (RO), nanofiltration membrane (NF), gas separation membrane, pervaporation membrane, and forward osmosis

membrane (FO). The polyamide is easily to be chlorinated because the nitrogen atom on amide bond is susceptible to chlorine due to the electrophilic character of the carbonyl groups. The chlorination process of polyamide consists of the substitution of chlorine atom for hydrogen atom of amide bond, accompanied by weakening or destruction of the hydrogen bonds between polymer chains (Xu et al. 2013). This process consists of two steps: positive chlorine attachment to the amide unit at the O atom with lone electron pair followed by rapid rearrangement to the N-Cl (Avlonitis et al. 1992; Jensen et al. 1999; Challis and Challis 2010). For aromatic polyamide, the chlorination process consists of not only the substitution process but also the chlorination of aromatic ring through an intermolecular rearrangement after amide chlorination, known as the Orton rearrangement which involves the transfer of the N-chlorine atom from a side amino group to a phenyl ring forming various aromatic substitution products under acidic condition (Kwon et al. 2006a, b). Although the chlorination process could also be affected by various other factors (Gabelich et al. 2002, 2005; Tessaro et al. 2005; Murphy 1991), it is generally accepted that this chlorination is closely related to the major chlorinating species in chlorine solution and their concentration (Glater et al. 1981, 1982).

The chlorination usually causes serious degradation of membrane chemical structure, ultimately resulting in membrane failure. Therefore, developing novel membranes with high chlorine resistant property is very important for the wide application of membrane separation technology.

Chlorine-Resistant Polymeric Membranes

Pejman Ahmadiannamini

Biomedical Engineering, University of Arkansas, Fayetteville, AR, USA

A chlorine-resistant polymeric membrane is mainly referred to a polymeric reverse osmosis (RO) desalination membrane that can withstand

exposure to chlorine and preserve its separation characteristics under such a harsh condition.

Currently, commercially available RO membranes are derived from two classes of polymers: cellulose acetate (CA) and aromatic polyamide (PA) (Li and Wang 2010). CA membranes are relatively low cost and tolerant to limited free chlorine. However, CA membranes suffer from some disadvantages such as a narrow operating pH range (4.5–7.5), susceptibility to biological attack, structural compaction under high pressure, and low upper temperature limit. On the other hand, PA thin film composite (TFC) membranes feature thin highly selective interfacially polymerized layers, which exhibit superior flux and salt rejections, wider operating temperature and pH range, and higher stability to biological attack, as compared with CA membranes (Park et al. 2008). Thus, PA TFC membranes used in RO are most preferred by the desalination industry. However, PA membranes encounter significant drawbacks in desalination processes, namely, membrane degradation under continuous exposure to trace amount of chlorine and deterioration of their performances.

Chlorine is the most common industrial oxidizing biocide in water treatment that is used for disinfection of domestic water and for the removal of tastes and odors from water. It is also typically used in RO treatment processes in order to control microorganisms that biofoul and clog the membrane. Consequently, water to be purified is often chlorinated, to disinfect it and ultimately inhibit biofouling of the membranes, and then dechlorinated before being fed to membrane desalination units. After passing through the membranes, the water is then rechlorinated before being sent to the distribution network. However, this requires additional equipments and chemicals and increased operating cost for the plant, accordingly.

When chlorine gas is added into water, it is hydrolyzed to form hydrogen ion, chloride, and hydrochlorous acids. The hydrochlorous can be further ionized to produce hypochlorite ions according to the following reactions (Geise et al. 2010):

Cl_2 , HOCl , and OCl^- are in equilibrium, and depending on the pH, different distributions of aqueous chlorine species are observed (Deborde and von Gunten 2008). The established chlorinating strength of these species is $\text{Cl}_2 \sim \text{HOCl} > \text{OCl}^-$ (Soice et al. 2003).

The amide nitrogen of the membrane is highly vulnerable to chlorine attack because of electron-withdrawing effect of carbonyl group. Upon exposure to free chlorine, N-H group is chlorinated to N-Cl group which can reversibly form the initial amid by treatment with reducing agents. The aromatic rings are also susceptible to attack by chlorine because it is an electron-rich region. Two possible chlorination mechanisms are proposed for aromatic rings, i.e., direct chlorination of the aromatic ring and Orton rearrangement, which involves initial chlorination of amid nitrogen followed by an intermolecular rearrangement, forming various aromatic substitution products (Fig. 1) (Raval et al. 2010).

According to the chlorination mechanisms, chlorine resistance of PA membranes largely depends on the chemical structures of the diamine components used. Aliphatic PA reversibly reacts with chlorine to yield N-chlorinated amide. Tertiary PAs are inactive towards oxidative chlorine. The Orton rearrangement takes place only when amide linkage is directly connected with benzene ring. Generally, the chlorine resistance increases in the order of PA synthesized from aromatic, cycloaliphatic, and aliphatic diamines, respectively.

Thus, the following modifications can be considered as potential strategies to enhance the chlorine resistance of PA membranes (Geise et al. 2010):

1. Replacing chlorine-sensitive amidic hydrogen on the amide linkages with other moieties, e.g., methyl ($-\text{CH}_3$) or phenyl ($-\text{C}_6\text{H}_5$)

Chlorine-Resistant Polymeric Membranes, Fig. 1 Proposed mechanism of chlorination of aromatic PA (Reprinted from *Desalination*, 250, Raval HD, Trivedi JJ, Joshi SV, Devmurari CV, Flux enhancement of thin film

composite RO membrane by controlled chlorine treatment, 945–949, Copyright (2010) with permission from Elsevier)

2. Replacing the aromatic ring bonded to the amide nitrogen with aliphatic chain or cyclics
3. Prevention of Orton rearrangement by adding protective groups at the possible chlorination sites on the aromatic rings

Other than PA, polysulfone has much better chlorine resistance as it has stronger chemical bonds. However, due to hydrophobic nature of polysulfone, introduction of controlled levels of hydrophilic groups, e.g., $-\text{SO}_3\text{H}$, while retaining its physical properties is necessary for polysulfone RO membranes. The polymer chain cleavage and side reactions, which can make it difficult to control the degree of sulfonation and molecular weight and consequently drop the mechanical and the thermal properties of polymer, can occur in the post-sulfonation method. The direct synthesis of the functionalized polysulfone from a sulfonated monomer is found to be more advantageous since the associated challenges can be avoided (Park et al. 2008).

Chloromethylation and Amination of Polymers (for AEM)

Pejman Ahmadiannamini

Biomedical Engineering, University of Arkansas,
Fayetteville, AR, USA

Chloromethylation (generally haloalkylation) of polymeric membranes followed by an amination reaction has been widely used for preparation of anion exchange membranes (AEMs). Significant efforts have been made to prepare AEMs from insoluble polymeric films such as polyethylene (PE), polypropylene (PP), polytetrafluoroethylene (PTFE), and polyvinylidene fluoride (PVDF). Such AEMs are typically prepared by grafting vinyl monomers such as styrene onto polymeric films and subsequent chloromethylation and amination modifications. Also, soluble polymers such as polystyrene (PS), polyether sulfone (PES), polyether ketone (PEK), or their blends or block copolymers have been widely used for preparation of AEMs. In such case, charged moieties can be introduced to the dissolved polymer via chloromethylation and amination reactions, either prior to the casting of polymer or after the casting into a film. Posttreatment, i.e., cross-linking of membranes, is often required to improve the chemical stability of AEMs prepared from soluble polymers (Xu 2005).

Chloromethyl groups can be introduced via Friedel-Crafts mechanism typically by reacting polymer with a chloromethylating agent, such as chloromethyl methyl ether ($\text{CH}_3\text{OCH}_2\text{Cl}$) or chlorotrimethylsilane ($\text{C}_3\text{H}_9\text{ClSi}$), using a metallic chloride (e.g., FeCl_3 , ZnCl_2 , or SnCl_4) as catalyst. Cross-linking of benzene rings with methylene bridges is encountered as a side reaction which would result in lower ion exchange capacity of final product according to the reaction presented in Fig. 1 (Jones 1952):

Alternatively, chloromethylation of polymers can be carried out using reaction mixtures which produce chloromethyl methyl ether in situ. These reaction mixtures are also known as chloromethylating complexes and may be, for example:

- Mixtures of paraformaldehyde and hydrochloric acid
- Mixtures of formaldehyde polymers and aluminum chloride
- Mixtures of methylal, thionyl chloride, and catalyst
- Mixtures of methylal, sulfonyl chloride plus chlorosulfonic acid, or chlorosulfonic acid only
- Mixtures of methylal, chlorosulfonic acid, and an oxygen-containing polar liquid

Among these complexes, the most commonly used are the ones that contain chlorosulfonic acid.

Chloromethylation and Amination of Polymers (for AEM), Fig. 1 Chloromethylation and methylene bridge crosslinking of polymers

Chloromethylation and Amination of Polymers (for AEM),
Fig. 2 Amination reaction of chloromethylated polymers

The reaction can be represented as (Boutier et al. 1980):

Positively charged groups are introduced to the chloromethylated polymer via amination reaction. The functional group of the AEMs can be weakly basic, such as primary, secondary, or tertiary amino groups which are obtained via reaction of chloromethylated polymer with ammonia or with primary or secondary amines, respectively. The amination reaction with tertiary amines, known as quaternarization, leads to AEMs with strongly basic functional groups (quaternary ammonium) (Helfferich 1995) (Fig. 2).

Chromium Transport Through Ion Exchange Membranes

Eugenio Bringas and Immaculada Ortiz
 Department of Chemical and Biomolecular Engineering, University of Cantabria, Santander, Cantabria, Spain

Occurrence and Removal of Hexavalent Chromium from Polluted Waters

The widespread use of chromium in industrial applications such as leather tanning, metallurgy, electroplating processes, and so forth has caused chromium contamination of surface and groundwaters (Pagilla and Canter 1999; Lin 2002; Rengeraj et al. 2001). Public concerns arise as a result of the sufficient evidence of chromium (VI) carcinogenicity in humans and the bioaccumulation into flora and fauna (IARC 1990; Kimbrough 1999).

Conventional processes reduce Cr^{6+} to Cr^{3+} , which is less toxic, less soluble, and less mobile than Cr^{6+} . Trivalent chromium is then converted to the hydroxide form and removed after precipitation (Hashim et al. 2011). Other technologies have been reported in literature as feasible

Chromium Transport Through Ion Exchange Membranes,

Fig. 1 Speciation diagram of Cr^{6+} in aqueous solution (Bringas et al. 2006a)

alternatives to achieve the removal and recovery of hexavalent chromium from wastewaters: adsorption and ion exchange (Mohan and Pittman 2006; Rivero et al. 2004), membrane processes (Bohdziewicz 2000) and separation processes based on the use of selective liquid membranes, especially emulsion liquid membranes (ELMs) (Salazar et al. 1992) supported liquid membranes (SLMs) (Kentish and Stevens 2001), non-dispersive solvent extraction (NDSX) (Bringas et al. 2012), and the emulsion pertraction technology (EPT) (Bringas et al. 2006a).

while in the acid range ($1 < \text{pH} < 7$), the coexistence of hydrogen chromate (HCrO_4^-) and dichromate ($\text{Cr}_2\text{O}_7^{2-}$) is expected. Therefore, the extraction of Cr^{6+} takes place through an anion-exchange mechanism, and thus, solvating and basic extractants are required.

The extraction of chromium by solvating extractants is based on the formation of an organic intermediate by the interactions between an electron donor (usually a phosphinic or a phosphoric moiety) and an electron acceptor (usually a proton) as shown by the following reaction which occurs in acid media:

Formulation of Selective Liquid Membranes for Hexavalent Chromium Removal

The main characteristics of the compounds to be employed as selective carriers in the formulation of selective liquid membranes in industrial applications are as follows: (i) high selectivity toward the target species, (ii) minimum extraction capacity of competing compounds, (iii) ease of regeneration, (iv) high solubility in low-cost solvents, (v) long-term stability, (vi) low cost, and (vii) not exhibiting toxic and carcinogenic properties.

Figure 1 shows the distribution of hexavalent chromium species in aqueous solution as a function of pH and the total chromium concentration (Bringas et al. 2006a). It is noticed that at basic pH values, the major species is chromate (CrO_4^{2-}),

where $\bar{S}$ is the solvating carrier and X^- represents the target species.

The commercial solvating extractants that employed the most on the removal of hexavalent chromium are TBP (tributyl phosphate marketed by Lanxess) (Venkateswaran and Palanivelu 2005), Cyanex 921 (trioctylphosphine oxide, TOPO, marketed by Cytec Industries) (Alguacil et al. 2004), and Cyanex 923 (a mixture of four trialkylphosphine oxides marketed by Cytec Industries) (Alguacil et al. 2004).

Tertiary amines and salts of quaternary amines represent the most important groups of basic extractants employed in the extraction of hexavalent chromium being the extraction mechanism described by the following ion-exchange reactions:

Salts of quaternary amines (chloride form)

Tertiary amines

where $\overline{QCl}$ is the chloride salt of a quaternary amine, $\overline{T}$ is a tertiary amine, and HY is a mineral acid.

Aliquat 336 (N-methyl-N,N-dioclyoctan-1-ammonium chloride marketed by BASF) (Bhowal et al. 2012) and Alamine 336 (mixture of tertiary amines with C₈ and C₁₀ groups marketed by BASF) (Bringas et al. 2006b) are the most reported commercial quaternary and tertiary amines employed in the removal of hexavalent chromium species.

Removal of Hexavalent Chromium from Polluted Groundwaters by the EPT Technology

Bringas et al. (2006a, b, 2007) reported the methodology for the optimal design of selective liquid membrane processes as efficient alternatives for the separation and selective recovery of hexavalent chromium from polluted groundwater generated by effluent leaking from surface deposition of industrial wastes. Furthermore, other competitive anionic species (mainly sulfate and chloride anions) were also present in the groundwater due to the specific location being close to the shore. The process should be designed to (i) reduce the chromium concentration in the polluted water below the disposal limit (0.5 mg L⁻¹) and (ii) obtain a concentrated chromium solution (>20 g L⁻¹) with negligible concentrations of sulfate and chloride anions. The design methodology is briefly illustrated in Fig. 2.

Chromium Transport Through Ion Exchange Membranes, Fig. 2 Design methodology of selective liquid membrane processes

Synthetic solutions that simulate the anionic composition of the real groundwater [Cr^{6+}] = 500–1,300 mg L⁻¹, [SO_4^{2-}] = 900–3,000 mg L⁻¹ and [Cl^-] = 300–1,000 mg L⁻¹, were employed as feed solutions. The pH of the feed solution was adjusted to 1.5 using H_2SO_4 . The organic solution was formulated as follows: 10 % (v/v) of Alamine 336 as the anionic extractant, 3 % (v/v) of Pluronic PE 3100 as surfactant, and Isopar L fluid as solvent. The emulsion was prepared by dispersing the stripping solution (NaOH 3–6 mol L⁻¹) in the organic phase at a volume ratio organic/stripping = 4/1.

After defining the separation system, the experimental and theoretical description of the extraction equilibria was performed following the guidelines reported in Fig. 2. In general, extraction systems involving ionic species are generally thought to reach chemical equilibrium at the interface, and thus equilibrium models of the chemical reactions are proposed. Table 1 reported the

extraction mechanism and the equilibrium parameters for the multicomponent system, Alamine 336/chromium/sulfate/chloride.

The emulsion pertraction technology (EPT) which combines the advantages of ELM, i.e., high efficiency due to large surface area for mass transfer, and SLM, i.e., extraction and stripping are performed in one step without dispersion of the organic phase into the aqueous feed phase, was selected as the most suitable configuration of the selective liquid membrane technology. More details about the technology can be found elsewhere (Bringas et al. 2006a; Bringas and Ortiz 2014). Kinetic experiments were performed in a laboratory experimental setup containing a membrane contactor Liqui-Cel[®] Extra-Flow 2.5 × 8 with fiber X-30 that provides an effective membrane area of 1.4 m². Figure 3 shows the evolution with time of the chromium concentration in the different fluid phases (feed, organic, and stripping) and a

Extraction reaction	Equilibrium parameter
$\text{HCrO}_4^- + \text{H}^+ + \text{R}_3\text{N} \rightleftharpoons (\text{R}_3\text{NH})\text{HCrO}_4$	$K_1 = 4.83 \text{ mol}^{-2} \text{ m}^6$
$\text{Cr}_2\text{O}_7^{2-} + 2\text{H}^+ + 2\text{R}_3\text{N} \rightleftharpoons (\text{R}_3\text{NH})_2\text{Cr}_2\text{O}_7$	$K_2 = 0.741 \text{ mol}^{-4} \text{ m}^{12}$
$\text{HSO}_4^- + \text{H}^+ + \text{R}_3\text{N} \rightleftharpoons (\text{R}_3\text{NH})\text{HSO}_4$	$K_3 = 1.37 \cdot 10^{-3} \text{ mol}^{-2} \text{ m}^6$
$(\text{R}_3\text{NH})\text{HSO}_4 + \text{Cl}^- \rightleftharpoons (\text{R}_3\text{NH})\text{Cl} + \text{HSO}_4^-$	$K_4 = 1.52$

Chromium Transport Through Ion Exchange Membranes, Fig. 3 Qualitative and quantitative evolution of the chromium concentration in the fluid phases (Feed solution: flows in continuous mode; Emulsion: recirculated)

photograph of the fluid phases at the end of the experiment. Similar extraction and back-extraction results were reported for sulfate and chloride anions (Bringas et al. 2006a).

The kinetic results confirmed the high selectivity of the carrier Alamine336 toward chromium species. The total chromium concentration decreased from 500 mg L⁻¹ at the module inlet to 0.8 mg L⁻¹ at the module outlet in one pass when the residence time in the module is 0.014 h. The chromium concentration in the stripping phase reached an average value of 14.6 g L⁻¹ after 1.3 h, and thus, a concentration factor of 18,733 was reached before depletion of the stripping reagent. From the analysis of the results obtained for the competitive species, it was concluded that the back-extraction process was not selective because all the species were totally back-extracted from the organic phase. For this reason the selectivity had to be controlled in the extraction step.

The kinetic analysis was completed with the proposal of the multicomponent separation mathematical model of the EPT process with the corresponding design parameters: (i) mass transport coefficients in the aqueous feed phase boundary layer (k_L), in the membrane (k_m), and in the organic phase stagnant layer ($k_o \cdot A_v$) for the different species involved in the separation-concentration process (see Fig. 4)

and (ii) the equilibrium parameters of the extraction reactions reported in Table 1. The model described satisfactorily the kinetics and selectivity of the separation-concentration EPT process under a wide range of operational conditions and served as a tool to perform the optimal design of the separation process (Bringas et al. 2006a).

Finally, a novel design methodology based on the application of mathematical optimization was developed in order to determine the optimal EPT process configuration able to achieve, at minimum cost, the separation and concentration objectives, (i) the contaminant removal up to the required concentration level ($[\text{Cr}^{6+}] < 0.5 \text{ mg L}^{-1}$) and, (ii) the selective contaminant recovery to obtain a concentrated solution that can be reused elsewhere ($[\text{Cr}^{6+}] 20 \text{ g L}^{-1}$). The different design alternatives were represented by means of network superstructures that were modeled through the developed EPT mathematical model, generating optimization problems that were solved following global optimization techniques (Bringas et al. 2007).

The procedure was illustrated for the treatment of an incoming groundwater stream with a known flow rate of 2.5 m³ h⁻¹ and a chromium concentration of 400 mg L⁻¹ (7.7 mol m⁻³). Comparison of the results obtained from the analysis of the different design alternatives concluded that a

Chromium Transport Through Ion Exchange Membranes, Fig. 6 Optimal process configuration for the emulsion phase

network configuration with three treatment modules combined in series and parallel and with a total membrane area of 591 m² was the most suitable process configuration to comply, at minimum cost, with the concentration specifications in the outlet streams. Figures 5 and 6 show the optimal networks for the aqueous feed solution and the emulsion phase, respectively.

Future Directions

Future development will require research and development activities in the following areas:

1. Evaluation of the operation cost (energy and material costs) to be considered in the formulation of the objective function

- employed to determine the optimal process network
2. Analysis of the long-term performance of the separation process to evaluate the stability of the selective carrier which guarantees the process economic viability
3. Rigorous evaluation cost of the optimal process network

Citric Acid Recovery by Electrodialysis

Gerald Pourcelly

Institut Europeen des Membranes, CC 047,
Universite Montpellier II, Place Eugene Bataillon,
Montpellier, France

Carboxylic acids such as lactic, succinic, gluconic, citric, and tartaric are widely used in food processing, detergent manufacture, and biodegradable plastic production (Bailly et al. 2001). Their production at the industrial scale is mainly achieved by mean of fermentation from molasses, starch hydrolysates, or sugars. Traditional processes to obtain these carboxylic acids consist on the precipitation of both the acids and their salts, so they can be isolated from the rest of the components of the raw material. Then, they are placed in an acid medium (sulfuric acid) to generate the acid form. A latter concentration step is carried out by evaporation followed by a crystallization. This generates large volumes of effluents with high salt contents. For example, typical yields of 1 kg of

Citric Acid Recovery by Electrodialysis,

Fig. 1 Scheme of a process of carboxylic acid production from fermentation. (EDC) concentration ED step, (EDBM) ED with bipolar membranes

citric acid are obtained per 2 kg of gypsum which is very difficult to dispose (Bialek and Ollis 1986). In order to reduce this environmental impact, the design of alternative production scheme was investigated. Extraction, adsorption, and membrane technologies, like electrodialysis (ED), were proposed to replace precipitation (Novalic et al. 1995). A complete scheme for carboxylic acid recovery is depicted in Fig. 1.

For EDC step of citric acid salts to the three dissociation constants of citric acid, the conductivity is mainly influenced by the pH value and the concentration. More ion dissociation leads to formation of further citric-acid-charged complexes in the solution which in turn causes electrical resistance reduction of the solution. The maximum ion density and consequently the minimum electrical resistance of the solution is obtained at pH 8 (Novalic et al. 1995). The EDBM step, which is water splitting by membrane electrodialysis, provides an attractive complement to the fermentation technology by removing the product acid while simultaneously providing an equivalent amount of base for use in adjusting the pH in the fermentor (Fig. 1). Moreover, the produced citric acid is usually at a relatively high concentration (0.5 M) so that the subsequent purification via crystallization or other techniques is relatively inexpensive (Xu and Yang 2002).

Cleaning Cycle of Fouled Membranes

Hongyu Li

UNESCO Centre for Membrane Science and Technology, The University of New South Wales, Sydney, Australia

Membrane Fouling

Membrane fouling is an unavoidable process in almost all industrial membrane applications. It refers to the deposition of foulants (solutes or particulates) on the membrane surface and/or inside the membrane pores during membrane separation process. Figure 1a demonstrates a typical membrane fouling structure in ultrafiltration (UF) and microfiltration (MF) systems.

The consequence of membrane fouling is the deterioration of membrane separation performance, which can manifest in two possible ways:

1. Decreased productivity, which can be observed in the reduction of permeate flux at a constant

Cleaning Cycle of Fouled Membranes, Fig. 1 Structure of membrane fouling layer in UF or MF filtration system (a) and observation of flux (b) or transmembrane pressure changes during fouling process

pressure operation mode (Fig. 1b) or increase in transmembrane pressure in a constant flux operation mode (Fig. 1c).

2. Changed separation efficiency in terms of selectivity of particular species, due to the altered surface characteristics by the buildup of fouling layer such as pore size, surface charge, or hydrophobicity.

While membrane fouling is unavoidable in most cases, the degree of fouling can be managed by using:

- (a) Appropriate membranes for a particular application
- (b) Appropriate pretreatment processes for the feed before the membrane process
- (c) Well-managed hydrodynamics in the membrane system and optimized operation system incorporating membrane cleaning process

Considerations for Membrane Cleaning

Understanding the properties of the feed including the main components as the potential foulants on

the membrane as well as understanding the fouling mechanisms of operation conditions such as applied pressure, shear rate on the membrane surface, operational temperature, the length of membrane operation, and the degree of membrane fouling could provide great insight for the selection of membrane cleaning protocols and the cleaning frequencies.

For example, microfiltration (MF) and ultrafiltration (UF) membranes used in the dairy industry for concentration of milk or removal of bacterial and spores would encounter components in the feed and potential foulants such as proteins as whey and casein, carbohydrates, fats, and minerals. Membranes used in reverse osmosis (RO) of seawater may experience organic fouling caused by humics, fulvic acid, carboxylic acid, and extracellular polymeric substances (EPS) as well as biofouling, which may involve adsorption of organic matter to membrane surface, continuous adhesion of microorganisms, growth of adhered cells, or subsequent formation of biopolymer matrix. Inorganic fouling or scaling initiated by supersaturation of minerals on the membrane surface is also common in RO, UF, and membrane distillation (MD) processes.

Operation conditions of a membrane separation process also affect properties of foulant accumulated on the membrane. For example, higher transmembrane pressure in RO, UF, and MF processes leads to higher convection of foulants to the membrane surface, resulting in a higher level of concentration polarization and eventually fouling. Higher pressure can also cause compaction of already formed foulant layer and make it more difficult to clean. Higher shear near the membrane surface causes higher back transport of foulant away from the concentration polarization layer and could reduce the formation of fouling layer on the membrane. On the other hand, the back transport of bigger foulants occurs preferentially over smaller ones, which could lead to the formation of foulant layer with smaller species, which could contribute in higher resistance and is more difficult to remove. Operation at higher temperature should lead to higher flux; however, denaturation of certain species such as protein could also lead to more difficulty in cleaning foulant layers.

Cleaning Cycle of Fouled Membranes,

Fig. 2 Stages of a cleaning cycle

Membrane Cleaning Process

The aim of membrane cleaning is to disrupt and remove foulants from the membrane surface and restore the membrane separation capability. The process is normally comprised of steps (as shown in Fig. 2) including draining of the feed solution from the membrane system, rinsing of loosely bound foulants with clean water, and chemical cleaning through breaking the cohesive and adhesive bonds between the foulants and between the foulant and the membrane. Sequential cleaning with a second chemical is also common for routine operations over repeated filtration and cleaning cycles over a long period.

Draining and rinsing before application of chemicals in membrane cleaning is very important. Without these steps, the majority of the chemical cleaner would be consumed by the residual feed instead of the foulants on the membrane surface and thus achieve low cleaning efficiency.

Rinsing should normally be conducted at the same temperature as cleaning to avoid compaction of foulants and normally takes 5–20 min.

During the chemical cleaning process, sufficient contact between the cleaning agent and the foulant is probably the rate limiting factor for cleaning reactions. This requires efficient transport of chemical to the foulant sublayer and rapid removal of the dislodged foulant away from the membrane. Appropriate chemicals should be selected that can attack the structure of foulant by cleavage of bonds within the foulant molecules and between the foulant aggregates, or solubilize the foulant deposits.

Chemicals for Membrane Cleaning

Selection of right chemical is most important for achieving an efficient cleaning reaction and process. Common chemicals used for membrane

Cleaning Cycle of Fouled Membranes, Table 1 Common chemicals used for membrane cleaning and their cleaning mechanisms

Chemical type (and simple chemical examples)	Cleaning mechanisms and applications
Caustic or alkaline (NaOH, KOH)	Hydrolysing, cleavage of disulphide bonds for protein aggregates for cleaning of protein foulants Saponificate fats and lipids Dissolve inorganic and organic foulants
Acidic (HCl, H ₃ PO ₄ , nitric acid, citric acid)	Solubilization and chelation for scale compounds and metal oxides Dissolving precipitates
Enzymatic cleaning (Protease, Lipase based commercial enzymes)	Cleave specific peptide bounds in the proteins Operate at conditions when enzyme activity was highest
Surfactants or wetting agents (Anionic, cationic surfactants)	Lower the surface tension of cleaning solution and increase solubility Displace foulants and prevent redeposition Improve contact between cleaning chemical and deposits
Oxidants (Free chlorine, NaOCl)	Oxidize foulant and increase hydrophilicity
Sanitizers and disinfectants	Used at the end of cleaning cycle or as part of the storage regime between uses

cleaning include alkaline or caustic chemicals such as sodium hydroxide used for hydrolysis and solubilize foulants, acids such as citric acid and nitric acid with solubilization function. Surfactants and detergents are also frequently used for emulsifying, dispersion, and surface condition purposes as shown in Table 1. Many membrane companies provide cleaning advice and procedures to their membrane products, some also have their own proprietary products. Many cleaning products are formulated with a mixture of chemicals that could include alkaline (or acidic), surfactants, and disinfectants.

Given their specific functions in cleaning mechanisms and the complexities of the feed and foulants, sequential cleaning, cleaning with one

type of cleaning agent followed by cleaning with the second chemical, can prove more effective in achieving higher overall efficiency. For example, acidic cleaners are often used in conjunction with alkaline cleaners to chelate calcium and magnesium ions that would otherwise form insoluble soap residuals. The acidification wash can also be applied to neutralize residual alkalinity and remove mineral deposits that may have formed during the alkaline cleaning or alkaline based enzyme cleaning.

Cleaning Conditions

Operating chemical cleaning at appropriate conditions such as circulation of the cleaning solution over the membrane surface provides mixing and shear force to the foulants from the membrane surface to the bulk.

With the selected chemicals and cleaning protocols, parameters such as concentration of cleaning agent, cleaning time, temperature, and hydrodynamic conditions during the cleaning process can all affect the overall cleaning efficiency. Chemical compatibility between the membrane and other filter components to the cleaning chemicals is also an important factor in selection of suitable cleaning chemicals. Membrane systems made of high chemical tolerances would allow greater freedom in selecting the composition, strength of cleaning solutions as well as the conditions for cleaning. On the other hand, milder cleaning conditions would have much less detrimental effect on the membrane integrity and life span as well as being more environmentally benign. Cleaning at higher temperature could lead to higher cleaning reaction and lower viscosity with high cleaning efficiency. However, optimized cleaning condition should be considered with the following factors in mind.

- Running costs in cleaning chemicals,
- Down-time,
- Membrane integrity over long period of time and
- Environmental impact for discharge of cleaning chemicals.

Summary

Membrane cleaning is an essential part of membrane operation system. Design and selection of cleaning protocol should start with the identification of potential foulants and the understanding of the membrane fouling process and mechanisms, followed by selection of appropriate chemical agents to the specific foulants. An effective cleaning process should start with proper draining of the feed and rinsing of the system prior to application of chemicals. Consideration of clean process design should include the membrane separation performance over many repeated cycles of fouling and cleaning, the effect on membrane integrity as well as overall operation and disposal costs.

membrane life while also minimizing expense and time.

Factors that influence the selection of membrane cleaning regime are listed in Table 1. Normally the chemical and temperature tolerance of membranes will be recommended or can be obtained from the membrane manufacturer. Inorganic membranes have a much higher tolerance of harsh chemicals and a higher temperature range than polymeric membranes.

The application with specific feed solution and operation conditions will dictate the foulants on the membrane and the strength of bonding between the foulant and foulant and the membrane. One example is membranes used in dairy application where the milk concentration would experience membrane fouling with protein as well as lactose and minerals. The cleaning of membranes used in dairy applications normally involves caustic cleaner in daily basis. On the other hand, membranes used in reverse osmosis (RO) would experience fouling by scale of calcium, ions, colloidal deposits, organic matter, and biological materials. The frequency of RO membrane cleaning ranges from once in a few month up to once a year.

An effective cleaning process should remove the foulants/deposits and other contaminants from the membrane surface and cassette feed channels and restore the membrane separation performance to a predictable, consistent level. This is usually evaluated by measurable parameters such as:

Cleaning Effectiveness

Hongyu Li

UNESCO Centre for Membrane Science and Technology, The University of New South Wales, Sydney, Australia

Cleaning effectiveness refers to how useful a cleaning regime is in regard to a specific application. An effective cleaning protocol to one application may not be very useful in another situation. An effective cleaning regime must accommodate a variety of factors in order to maximize

Cleaning Effectiveness, Table 1 Factors and considerations for selection of membrane cleaning protocol

Factors	Consideration for clean
Membrane material (polymeric, inorganic)	Tolerance to chemical and temperature could affect membrane lifetime
Feed composition and the degree of fouling	Specific chemicals and regime to specific foulants and degree of fouling Frequency of cleaning relates to costs and membrane lifetime
Membrane module configuration (flat sheet, hollow fiber, spiral wound)	Amount of cleaning solution required and operation conditions of cleaning

(a) Clean water permeability

This can easily be estimated by measuring membrane flux of clean water at defined operation conditions, for example, at fixed pressure and temperature. Low recovery of clean water permeability indicates an insufficient cleaning process.

However, this parameter is not always reliable for evaluation of cleaning effectiveness. A good clean water permeability recovery does not always represent a total removal of foulants from membrane. In some situations, a partial removal of the residual foulant does not contribute significantly to clean water permeability, and the separation performance in subsequent operations could be exasperated due to the existing residual foulant.

(b) Analysis of flush solution after cleaning can also be used to indicate the presence of foulant in the system after cleaning.

Apart from these methods commonly applied in cleaning-in-place (CIP) applications that do not affect continued membrane usage and functioning, other techniques that require removal of membrane from module and sometimes destruction of membrane can also be applied for diagnostic procedure, including:

(c) Analysis of membrane surface properties, such as surface charge, contact angle, and elemental analysis of species as well as SEM imaging on the membrane, which can be used to observe the extend of the amount of residual foulants on the membrane.

separation performance. Cleaning efficiency is commonly measured by either the membrane flux recovery or resistance removal (Li and Chen 2010).

The flux recovery is estimated by the comparison of membrane water fluxes before fouling and cleaning and water flux after cleaning. The flux recovery can be estimated as

$$\text{Flux Recovery} = \frac{J_{wc}}{J_{wi}} \times 100 \% \quad (1)$$

where J_{wc} is the water flux after cleaning and J_{wi} is the water flux before the membrane was subjected to fouling.

The resistance removal can be estimated as

$$\text{Resistance Removal} = \frac{R_r - R_c}{R_r} \times 100 \% \quad (2)$$

where R_r is the membrane resistance before cleaning and R_c is the membrane resistance after cleaning. The membrane resistance is estimated with clean water flux of membranes at different stages of operation with

$$R = \frac{\Delta P}{\mu J} \quad (3)$$

where J is the water flux, ΔP is the transmembrane pressure of water flux measurement, and μ is the viscosity of water (at the temperature of water at the flux measurement).

This type of assessment involves measurements of membrane fluxes prior the filtration process, the initial water flux (J_{wi}), membrane flux at the end of filtration process (J_{wf}), membrane flux after rinsing (J_{wr}), and membrane flux after cleaning (J_{wc}).

Analytical methods can be used to evaluate the changes of membrane surface properties such as charge and contact angle before and after cleaning. Infrared and X-ray photoelectron spectroscopy of the cleaned membrane has also been used in identifying remaining foulants on the cleaned membrane.

A “cleaned” membrane subject to extensive extraction methods can reveal not only the amount of residual foulant on the membrane but also the composition foulants left on the membrane after cleaning. This information can be very useful to

Cleaning Efficiency

Hongyu Li

UNESCO Centre for Membrane Science and Technology, The University of New South Wales, Sydney, Australia

Cleaning efficiency measures how well the cleaning process is in recovery of the membrane

formulate sequential cleaning strategies by using one agent to clean one part of the foulant and a second, more effective, agent in removing the remaining of the residual.

One example is the cleaning of membrane used in whey protein filtration. Through analysis of foulants extracted from the membranes before and after cleaning with gel electrophoresis (SDS-PAGE) technique for protein composition, it was revealed that the high molecular weight components in the foulant layer could be more easily cleaned than the smaller components. Sequential cleaning using NaOH for removal of large protein followed by HCl solution for cleaning of smaller molecules has shown consistent performance restoration over repeated cleaning cycles (Norazman et al. 2013).

Parameters Affect Cleaning Efficiency

Both the properties of cleaning solution (concentration, pH) and the operational condition (pressure, temperature, velocity, and cleaning time) could affect the outcomes of cleaning.

Generally speaking, conditions that favor the contact between the cleaning chemical and the reaction rate would be beneficial for efficient cleaning. For example, cleaning solution of higher concentration would have a higher rate of reaction with foulants, higher temperature improves reaction rate, and cleaning time relates to contact and reaction time. High circulation rates also lead to more turbulence and high shear rate which favors removal of dislodged foulants from the membrane. Low pressure could avoid redeposition of foulant.

However, practical experience suggests that for specific cleaning applications, the optimum cleaning conditions should be determined on considerations of limiting conditions of all those factors. For example, the integrity of membrane material and hosing material could be compromised at temperature above their tolerance level. Extensive circulation at high flow rate relates to higher energy cost.

Cleaning-in-Place (CIP) Systems

Hongyu Li

UNESCO Centre for Membrane Science and Technology, The University of New South Wales, Sydney, Australia

Cleaning-in-place (CIP) is a method of cleaning closed systems in industrial settings, such as interior surfaces of pipes, vessels, heat exchangers, process equipment, filters, membrane systems, and their associated fittings without disassembling.

Opposed to cleaning-in-place is disassembled cleaning, which refers to a method of cleaning that works by disassembling the closed systems and cleaning individual components (often manually) before assembly for continued usage. Many laboratory facilities and small-scale systems are commonly cleaned and disinfected this way.

For industry-scaled applications, with systems that require frequent internal cleaning and high level of hygiene, such as dairy processing, beverage processing, processing of food, bioprocesses, and pharmaceutical applications, automated cleaning-in-place provides great benefits of faster, safer, and reliable cleaning processes which is very important for industrial considerations.

The purpose of membrane cleaning is to remove foulants and deposits on the membrane surface and membrane pore structure to restore the

membrane separation capabilities that had been compromised by membrane fouling.

Many membrane foulants behave as cohesive solids ranging from soft macromolecular gels to hard mineral scales on the surface. Breakdown of these foulants may include dissolution or solubilization, disruption of cohesive interactions between aggregates within the deposit, or disruption of the adhesive forces that bind foulant particles/molecules to the surface.

The common practice of cleaning-in-place of membrane system often involves a combination of hydraulic and chemical cleaning in three distinctive steps:

1. Draining before cleaning. The membrane operation (e.g., filtration of milk) is stopped and the transmembrane pressure is released to allow relaxation and redistribution of the foulant into the feed stream. The feed solution is then drained.
2. Rinsing. This involves replacing feed with clean water in circulation at low pressure to flush and remove loose foulants from the membrane surface.
3. Chemical cleaning. This introduces the cleaning solution into the membrane system, allowing circulation at low pressure in order to break down foulant structure and increasing solubilization of foulant species from the membrane surface.

Selection of chemical cleaning agent should consider:

- Compatibility between the cleaning chemical and the membrane material and fitting components.
- The cleaning agent should be safe and does not pose as potential contaminants to the product.
- Disposal of the cleaning chemicals.

Selection of cleaning process operation condition should consider:

- Overall downtime from production
- Temperature tolerance of membrane material
- Cost of energy for cleaning

Common cleaning agents used by industry for CIP include acids, bases, enzymes, surfactants, disinfectants, and steam and gas sterilization (Mulder 1996), depending on the feed composition and severity of fouling.

Alkaline cleaners, particularly sodium hydroxide and potassium hydroxide, with their ability to dissolve protein molecules, fats, and other precipitated materials, have been used to clean membranes fouled with proteins.

Acidic cleaners include nitric acid, hydrochloric acid, and phosphoric acid, and better cleaning results with HCl for the membrane fouled with milk components have been reported. Acidic cleaners have potential for dissolving precipitates formed during the cleaning procedure.

Enzymatic cleaners have the unique benefits of being biodegradable and more environmentally friendly. Enzymatic cleaners possess great potential to remove proteinaceous matter from the membrane. Proteases are the most commonly used enzymatic cleaners with their function of hydrolyzing peptide bonds in the proteins which leads to the disassembly of protein (Petrus et al 2008). However, a major concern associated with enzymatic cleaning is the possibility of membrane fouling by the enzyme molecules employed in the cleaning process.

Surfactants can be used to improve the contact between the cleaning chemicals and the foulant, thus improving the reaction rate (Trägårdh 1989).

Quite often, better cleaning performance can be achieved by combining cleaning agents or sequential cleaning.

Closed-Loop Cascade Diafiltration

Greg Foley

School of Biotechnology, Dublin City University,
Dublin, Ireland

Closed-loop cascade diafiltration (Charcosset 2012) is used when the product to be recovered appears in the permeate of the first stage of a two-stage process. It is similar to ► [open-loop cascade](#) diafiltration but differs in that the permeate from the second stage is recycled and used as the diluant of the first stage. A schematic is shown below (Fig. 1).

The obvious advantage of this approach over the open-loop configuration is the reduced requirement for a fresh diluant. In principle, the product should have a low rejection coefficient in the first stage and a high rejection coefficient in the second stage.

CO Selective Oxidation

Giuseppe Barbieri

Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

Hydrogen purification is a critical technology for many chemical and petrochemical processes and power generation by PEM-FCs (proton exchange membrane fuel cells) as well. Carbon monoxide is, in fact, a poisoning or inhibitor for most catalysts such as the Fe_3O_4 one involved in ammonia synthesis or the platinum-based one used at a low temperature in PEM-FCs. In the latter case, in order to avoid cell performance degradation, carbon monoxide concentration must be kept below 10 ppm in the hydrogen feed streams.

CO selective or preferential oxidation is the primary method used for hydrogen deep purification (Avgouropoulos and Ioannides 2003), and different research groups (Manasilp and Gulari

2002; Souza et al. 2007; Bissett and Oh 2005; Woortsch et al. 2004; Sirijaruphan et al. 2004; Kotobuki et al. 2005) work on this topic. The involved reactions are:

Therefore, a catalyst active for CO oxidation in the presence of high concentrations of H₂, CO₂, and steam is required to avoid H₂ consumption, nor should it have a strong preference to the water-gas shift reaction since in these conditions of temperature and gas composition, the equilibrium gives ca. 0.5–2 %mole of CO.

Both alumina-supported Pt and Au catalysts have been found to be active for CO Selox (Luengnaruemitchai et al. 2004). Pt-based catalysts require high temperatures (about 170 °C) and a high feed molar ratio O₂/CO (about 1.5) for complete CO depletion, with a corresponding loss of selectivity (typically 34 %). Water vapor has a positive effect on these catalysts, increasing the conversion without changing the selectivity; instead CO₂ has a detrimental effect (Avgouropoulos et al. 2002). Au-based catalysts are more active than platinum catalysts at relatively low temperatures (<120 °C) but not so resistant toward deactivation by CO₂ and H₂O. Promoted Pt/Al₂O₃ catalysts (e.g., with Ru or Rh) have also been investigated. Values of ca. 15 ppm of CO in the reactor outlet are reported for a microreactor (Pt–Ru/α-Al₂O₃ catalyst) operated with a O₂/CO feed molar ratio of 1.5 and 4 (Delsman et al. 2004; Cominos et al. 2005). Whereas, values of CO less than 10 ppm were reported for a fixed bed reactor using a O₂/CO feed molar ratio of 2.5 (Dudfield et al. 2000). Other interesting active and very selective catalysts are CuO–CeO₂ mixed oxides (Avgouropoulos and Ioannides 2006; Zou et al. 2006); however, the presence of H₂O and CO₂ in the feed causes a significant decrease in their activity (Avgouropoulos et al. 2005).

Apart from the improvement of the catalyst, new reactor concepts are being studied. Monoliths present different advantages over particulate catalysts, including pressure drop reduction, ease of handling, structural robustness, and possibly

increased heat transfer. Interesting new engineering devices such as catalytic membranes and catalytic membrane reactors were investigated in a few papers for CO selective oxidation (Hasegawa et al. 2001, 2002; Bernardo et al. 2006). The concept of using Pt in zeolite catalysts was applied for this reaction by Watanabe et al. (1995; Igarashi et al. 1997). In a recent paper (Kotobuki et al. 2005), a significant improvement of CO conversion and selectivity with high Pt dispersion in the zeolite (ZSM-5) pores was demonstrated. Zeolites play host to noble-metal clusters for numerous catalytic applications, and well-defined clusters of narrow size distribution down to 1 nm have been obtained under suitable conditions (Pan et al. 1990; de Graaf et al. 2001). Investigations on the use of large-pore diameter zeolite such as Pt-loaded FAU-type membranes (Bernardo et al. 2006) show also the possibility of collocating a membrane reactor CO selective oxidation stage (operating at 200–220 °C and with a feed ratio O₂/CO = 1) after the low-temperature water-gas shift reactor in a reforming plant. One of the findings of this study was the possibility of improving CO removal by increasing the operating pressure.

A zeolite catalytic membrane provides catalytically active and nano-sized particles entrapped in a thin zeolite layer (a few microns thick), resulting in:

- Efficient reactant/catalytic phase contact, reducing bypassing and misdistribution generally shown in a packed bed
- Short and narrow distributed contact time
- Hot spot control that is beneficial since a local temperature increase can lead to promotion of reverse water-gas shift reaction (Ouyang and Besser 2005; Ouyang et al. 2005)

With this aim, catalytic Pt-loaded zeolite membranes were utilized as an effective device for CO selective oxidation in a single-stage membrane reactor operating in a continuous *flow-through* configuration at ca. 200 °C and a low feed molar ratio O₂/CO = 1 and 1.5 (Bernardo et al. 2008). This new model reactor design leads to improved and really interesting performance in terms of CO conversion and limited hydrogen consumption.

Coacervation

Emma Piacentini

Institute on Membrane Technology, National Research Council, ITM-CNR, Rende, Italy

Coacervation is a chemical method for producing polymer droplets in suspension based on the separation of two liquid phases into one concentrated colloidal phase, being the coacervate, and another highly dilute colloidal phase (Fig. 1). The phase

Coacervation, Fig. 1 Coacervate formation. (a) Intrapolymers complex, (b) soluble aggregate of intrapolymers complexes, (c) coacervate with dense and dilute domains, (d) coacervates picture

Coacervation, Fig. 2 Complex coacervate gels formed by mixing a polyanion polymer with a polycation polymer

separation of a single polyelectrolyte or a mixture of polyelectrolytes from a solution and deposition of the agglomerated colloidal particles (i.e., the matrix material) on an immiscible active core results in the formation of a simple coacervate or a complex coacervate, respectively (De Kruijff et al. 2004).

Phase separation in simple coacervation is brought about by addition of a salt, pH, or temperature change in the polymeric solution (such as alginate and calcium) while in complex coacervation is brought about by anion–cation interactions (such as gelatine and gum Arabic or chitosan and alginate). Complex coacervate gels can be formed by mixing of a polyanion with a polycation (Fig. 2). The underlying principle of this method is that polymers with opposite charges stick together and form soluble and insoluble complexes depending on the concentration and pH of the respective solutions. One such example is coacervating proteins with polysaccharides (Schmitt and Turgeon 2011).

Coacervation, Fig. 3 Microscopic view of the microcapsules obtained by complex coacervation

Proteins below its isoelectric point are positively charged and likely to associate with anionic hydrocolloids and form polyion complex hydrogel (complex coacervate).

Coacervation uses the principle of difference in ionic forces to cause the polymer(s) to form droplets and drop out of solution. A key to this is knowledge of the isoelectric point (PI) of the polymers and adjusting the formulation accordingly. Electrostatic effects and other weak energy interactions, especially hydrogen bonding, play a very important role during complex formation/coacervation between proteins and polysaccharides. Hydrophobic interactions can also make a significant contribution to formation of complexes and coacervates between oppositely charged biopolymers. Several physicochemical parameters influencing the overall and local charge of the protein and the polysaccharide play an important role in the control of the phenomenon such as pH, ionic strength, protein to polysaccharide ratio, and total biopolymer concentration. Some other parameters such as the biopolymer molecular weight and flexibility, the charge density, the stirring, the pressure, or the temperature have been shown to also influence complex formation.

Complex coacervation between oppositely charged proteins and polysaccharides is a well-known oil encapsulation technology (Fig. 3).

Typical steps of encapsulation by complex coacervation generally involve:

1. Emulsification (formation of the core) of a generally hydrophobic material in a solution comprising hydrocolloids
2. Coacervation (formation of the shell) implying the formation of a coacervate phase
3. Wall hardening (usually achieved by cross-linking the hydrocolloid forming the wall)

The step of wall formation is generally driven by the surface tension difference between the coacervate phase, the water, and the hydrophobic material. In most industrial coacervation processes, one of the hydrocolloids used in coacervation processes is selected from gellable proteins. These are easier to use and less prone to aggregation after the formation of the wall when the temperature is below the gelling temperature, if

compared to non-gellable hydrocolloids. Gelification, in turn, is generally brought about by lowering the temperature of the reaction mixture below the gelling point of the gellable hydrocolloid. The emulsification step can be carried out by homogenizing the oil with an aqueous sol of one colloid and mixing the emulsion with an aqueous sol of another colloid, or the two sols may be made and mixed and the oil emulsified therein. Complex coacervation occurred by lowering the pH until a pH is low enough to enough opposite electrical charges and form polymer complex. The coacervate phase is fluid and distributes over the oil surface forming the shell. The wall hardening renders the process irreversible and making the resulting microcapsules insoluble in water, resistant to mechanical stress and to heat exposure.

Coagulation Bath

Silvia Simone

Institute on Membrane Technology, National Research Council, ITM-CNR, Rende, Italy

Phase Separation (PS) or Phase Inversion (PI) is among the principal techniques for membrane preparation. The membrane matrix and the

membrane pores are formed, respectively, from the polymer-rich and the polymer-lean phases originated by the phase separation of an initially homogeneous polymeric dope. Immersion of a cast (or spun) polymeric dope in a coagulation bath is normally used in nonsolvent (or diffusion)-induced phase separation (NIPS or DIPS), also called immersion precipitation (IP), to achieve such separation, often referred to as demixing or precipitation as well. Upon immersion in the coagulation bath, the initial composition of the dope changes as the solvent diffuses in the bath and is gradually replaced by the nonsolvent. Polymer precipitation due to solvent/nonsolvent (S/NS) exchange is exploited both in flat sheet and hollow fiber preparation via NIPS. However, for flat sheet membranes, the cast polymer film is immersed in the coagulation bath and phase inversion starts at the top surface of the film. Regarding hollow fibers, prepared via wet or dry/wet spinning, phase inversion takes place both at the inner and at the outer surfaces. While the term “coagulation bath” is normally used when referring to the media for the coagulation of the outer surface, the inner coagulant is often referred as bore fluid. In any case, the solvent/nonsolvent exchange is at the basis of the membrane preparation mechanism via immersion precipitation. Phase separation will occur only when the system composition, in terms of polymer/solvent/nonsolvent (P/S/NS) concentrations, reaches the miscibility gap, surrounded by the spinodal curve in the ternary phase diagram (at a selected temperature). Membrane morphology will be strongly affected by the coagulation bath composition and temperature, since they both influence the solvent/nonsolvent exchange rate and the polymer precipitation. In particular, the exchange rate depends on the mutual affinity between the solvent contained in the dope and the nonsolvent in the bath as well as on temperature. On the other hand, diverse nonsolvents usually display different coagulation power; polymer precipitation is affected by the nonsolvent nature and, obviously, by temperature. The mutual affinities between S/NS and P/NS are

often described in terms of Hildebrand's solubility parameters (δ). In general, it is known that the closer the values of the solubility parameters of two species, the higher the affinity between the two. Therefore, the difference between the S and the NS solubility parameters (δ_{S-NS}) can be used as a reference to estimate the S/NS exchange rate during coagulation: it will be faster if they have high mutual affinity, indicated by a small δ_{S-NS} . Furthermore, the difference between the P and NS parameters (δ_{P-NS}) can be used to infer about the coagulation power of a nonsolvent: strong, or harsh, coagulants are characterized by a higher δ_{P-NS} , while soft, or gentle, nonsolvents usually display a smaller δ_{P-NS} . The Hildebrand solubility parameter can be calculated, according to the Hansen's theory (Hansen 1967), as the square root of the sum of the squares of three components: δ_d , representing the energy from dispersion bonds; δ_p , the energy from dipolar intermolecular forces; and δ_h , the energy from hydrogen bonds between molecules. The strength of different NS can be also evaluated and, eventually, compared, by looking at the position of the binodal curve in the ternary phase diagram. In general, the curve moves towards higher NS percentages when using a softer coagulant. On the contrary, the binodal curve moves closer to the P-S axis, indicating less NS tolerance, when using a strong coagulant. The temperature of the coagulation bath will influence the interdiffusion rate between solvent and nonsolvent, which will be faster at higher temperatures. Polymer solubility in the S/NS mixture at any time during phase inversion depends on temperature, which affects the miscibility gap boundary position in the ternary phase diagram; this will mostly depend on the initial temperature of the casting solution but is affected by the coagulation bath temperature as well. Another factor that is known to affect the S/NS exchange rate is the molecular weight, since bigger size normally hinders diffusion. Solvent diffusion in the coagulation bath can be delayed by acting on the concentration gradient, i.e., by adding some solvent in the bath composition; this will also reduce the difference between the solubility parameters

of the polymer and the coagulant, which is not pure nonsolvent. The proper choice of the coagulation conditions allows to tailor membrane morphology. In general, it is known that membranes with open and porous structures can be obtained by fast demixing, while delayed demixing often results in the formation of a dense skin, with sponge-like or closed-cell morphology in the sublayer. Furthermore, fast demixing is one of the factors inducing macrovoids formation. For instance, when the as-cast polymer film is immersed in the coagulation bath, the polymer precipitation in the top layer will be faster with a strong coagulant, resulting in a porous skin; on the contrary, delayed demixing may result in the formation of a dense skin. However, the S/NS exchange can be properly delayed, by introducing some solvent in the coagulation bath or by using a soft coagulant, as a viable strategy to reduce macrovoids formation; in fact, it is accepted that the nonsolvent influx is responsible for voids growth during membrane formation.

Coagulation Medium

Francesco Galiano
Institute on Membrane Technology, National
Research Council, ITM-CNR, Rende, Italy

Synonyms

Coagulation medium (also known as nonsolvent bath, coagulation bath, phase-inversion medium, precipitating medium)

Definition

It is a liquid bath providing the precipitation of an extruded or cast polymer solution with the resulting formation of a solid membrane matrix.

Coagulation medium is responsible for the phase inversion process, and most of the time, it is represented by water. Some organic solvents (such as ethanol or isopropanol) can be also used to induce polymer precipitation, and even vapors and supercritical fluids can be considered as coagulation media for the phase inversion process.

In non-solvent-induced phase separation (NIPS), the polymer solution is cast upon a support and subsequently immersed into a coagulation bath (generally water) where polymer precipitation occurs. The choice of the appropriate coagulation medium represents a significant aspect in membrane preparation. The miscibility between solvent (in which the polymer is dissolved) and non-solvent can affect, in fact, the final structure of the membrane. The solvent contained in the cast film exchanges with the non-solvent contained in the coagulation medium inducing polymer precipitation.

Variable amounts of solvents can be also added to the coagulation medium giving two contrary effects:

Slow down the phase separation process leading to the formation of membranes with a less porous structure.

Decreasing polymer concentration at film interface leading to a membrane with a more open structure (Drioli and Giorno 2009).

Final membrane structure will, thus, depend on the miscibility between the two liquids and, therefore, on the mutual interactions established between them.

Even the temperature of the coagulation medium, used to precipitate the casting solution,

plays an important role. Generally low temperatures lead to the formation of membranes with a more dense structure (delay demixing) that find application in nanofiltration, gas separation, or reverse osmosis.

In vapor-induced phase separation (VIPS), the coagulation medium is represented by a non-solvent in a vapor phase. The vapor is generally water, and the precipitation occurs due to the affinity of the solvent (contained in the polymeric solution) for vapor (contained in the surrounding environment). VIPS technique leads to the formation of membranes with a porous structure usually applied in microfiltration. Relative humidity, temperature, and exposure time are the main variables affecting membrane morphology.

Other possibilities are supercritical fluids such as supercritical CO₂ that can be used as coagulation medium. Supercritical CO₂ can be used, in fact, as environmental friendly non-solvent leading to the formation of asymmetric membranes with the advantage of avoiding the collapse of membrane structure due to absence of a liquid–liquid or a liquid–vapor interface (Reverchon and Cardea 2004).

Cobalt Removal and Recovery by Supported Liquid Membranes

Carlos Moreno

Department of Analytical Chemistry, Faculty of Marine and Environmental Sciences, University of Cádiz, Puerto Real, Spain

Synonyms

Co (II) ions separation by supported liquid membranes

Naturally found in some minerals as cobaltite, erythrite, or smaltite, cobalt is an element with different industrial applications, mainly in, i.e., electroplating and magnets or, as alloying element, for the fabrication of engines with high resistance to temperature.

Some cobalt salts have the ability of giving blue color, and, then, they have been extensively used as pigment for ceramics, glass, inks, etc.

Supported liquid membranes have been used as a tool for the recovery and removal of cobalt from different waste aqueous solutions. Typically, these solutions contain a mixture of metals that may complicate the selective separation of cobalt. Thus, in many cases, separation of cobalt by supported liquid membranes has to be performed in the presence of metals such as copper, cadmium, chromium, and specially nickel, which exhibits similar properties than cobalt. For a good and selective separation of cobalt ions from the rest of metallic element separation, it is essential to control the chemical conditions of the membrane separation process, mainly the correct selection of the organic carrier and the acidity of the aqueous source phase.

The mechanism of the separation process of cobalt by supported liquid membranes is based on the complexation and de-complexation reactions of cobalt ions present in the aqueous solution, with an extractant agent present in the organic liquid membrane. Although many organic reagents have been studied and applied at laboratory scale, the best

results have been obtained when using organophosphorus acidic compounds, such as bis(2-ethylhexyl) hydrogen phosphate (1) or bis(2,4,4-trimethylpentyl) phosphinic acid (2) (Fig. 1).

Cobalt Removal and Recovery with Strip Dispersion

Gerardo León

Departamento de Ingeniería Química y Ambiental, Universidad Politécnica de Cartagena, Cartagena, Spain

The commercial success of supported liquid membrane has been seen to be limited due to the lack of long-term stability. Six mechanisms have been identified for supported liquid membrane instability (Kemperman et al. 1998). The two considered most important are emulsification of the liquid membrane phase and osmotic pressure difference over the membrane. In order to increase the stability of a supported liquid membrane (increasing simultaneously the efficiency of the separation process) by preventing the loss of the liquid membrane process, the use of the supported liquid membrane with strip dispersion has been described. This technique, first described by Ho (2001a), incorporates concepts of supported liquid membranes and of emulsion liquid membranes. It is also known as pseudoemulsion-based hollow-fiber strip

dispersion (PEHFSD), dispersion supported liquid membrane (DSLML), or emulsion pertraction (EP) due to the different configurations that have been used, mainly flat-sheet and hollow-fiber supported liquid membranes configurations. It has been applied to the removal and recovery of different organic species (organic acids, phenols, antibiotics, and alkaloids) and different metals (Co(II), Cr(VI), Cr(III), Cu(II), Au(III), etc.). Figure 1 shows a schematic representation of the technique.

As shown in this figure, the aqueous product phase, containing the stripping agent, is dispersed in the membrane organic phase, containing the carrier, and the water in oil dispersion formed is added (flat-sheet configuration) or is passed (hollow-fiber configuration) onto one side of the membrane support. The organic phase of the dispersion becomes imbedded in the pores of the microporous hydrophobic support of the flat or hollow-fiber configuration, forming a stable SLM. The constant supply of organic membrane solution into the pores of the membrane support ensures stable and continuous operation. The aqueous feed solution is added or passed on the other side of the membrane support, and the target specie is extracted into the organic solution by the selective carrier and then stripped by the aqueous strip solution (Fig. 1). For final recovery of the target specie, the mixer is turned off or a settler is used for the loaded strip dispersion, and the dispersion quickly separates. Supported liquid membranes with strip dispersion processes offer

Cobalt Removal and Recovery with Strip Dispersion, Fig. 1 Schematic representation of the carrier mediate counter-transport of cobalt (II) through supported liquid

membranes with strip dispersion using an organophosphorus acid as carrier

several advantages compared with other liquid membrane configurations, including the following (Klaassen et al. 2005): no emulsion formation in the water phase, flexible process parameters, phase separation is not necessary, compact modular equipment, low energy consumption, and large specific surface areas due to hollow-fiber contactors. This technique has been used for cobalt removal and recovery (Ho 2001b; Alguacil et al. 2011). Ho described several experiments using polypropylene as polymeric microporous support, in both flat-sheet and hollow-fiber configurations, di(2,4,4-trimethylpentyl)dithiophosphinic acid (Cyanex 301) as carrier, Isopar L and dodecanol as organic diluent, and sulfuric acid as stripping agent. Alguacil et al. removed cobalt (II) from acidic sulfate solutions by using polypropylene as polymeric microporous support in hollow-fiber configuration, di(2-ethylhexyl) phosphoric acid (DP-8R) as carrier, Exxsol D100 as organic diluent, and sulfuric acid as stripping agent.

Cold Plasma

Antonella Milella and Fabio Palumbo

- [Hollow Fiber](#)

Plasma can be defined as a partially ionized gas which contains approximately equal numbers of positive and negative particles (Chapman 1980;

Chen 1974; Grill 1994; Thornton and Greene 1994; d'Agostino 1990; Milella 2008).

Plasmas can be roughly classified into hot plasmas (also defined as near-equilibrium plasmas) and cold plasmas (or nonequilibrium plasmas). Hot plasmas are characterized by very high temperatures of electrons and heavy particles (atoms, molecules, or ions) and they are almost fully ionized. In cold plasmas, instead, the electron temperature is relatively high (1–10 eV), while the translational energy of heavy particles remains very low, with temperature close to the room one and the ionization degree is typically low (around 10^{-4} – 10^{-6}). When an electric field is applied to a gas, energy is transferred more efficiently to the free electrons naturally present in the gas than to the ions. The accelerated electrons, then, transfer the energy to heavier particles through elastic and inelastic collisions. At low pressure the collision frequency is very low; moreover, because of the large mass difference between electrons and heavy particles, the transfer of kinetic energy is inefficient. Hence, in this nonequilibrium state, the gas temperature cannot increase, while electrons gain enough kinetic energy to promote excitation, ionization, fragmentation, and formation of reactive species by inelastic collisions with heavy particles. In this scenario, energetic electrons can produce high temperature chemistry in a gas at low temperature, and this allows the treatment of thermally sensitive materials like polymers.

Since electrons are much faster than other particles, every surface immersed in the plasma immediately develops a negative charge which accelerates ions. As a matter of fact, the plasma potential is always the most positive one.

A low-pressure cold plasma apparatus typically consists of a vacuum chamber, a pumping unit, a gas feeding system and gas controllers, pressure gauge, a power supply, and a power transfer device. Electrodes can be driven both by AC and by DC power supply. AC discharges, commonly run in the radiofrequency (RF) and microwave (MW) range, are more stable and suitable for insulators (e.g., ceramic and polymers) processing. In case of RF glow discharges, the operating frequency is generally 13.56 MHz in order to avoid interferences with

communications. At this frequency, only electrons can follow the instantaneous variations of the applied electric field, while ions are driven by an average potential.

At the steady state, the total ion and electron charge flow to a given electrode during an RF cycle must balance to zero and a self-bias that is negative with respect to the plasma potential develops. If the surface is electrically isolated, the potential at the steady state is named floating potential and it is also negative with respect to the plasma potential. As a consequence, each surface immersed in a plasma will be bombarded by ions.

It should be also highlighted that cold plasmas can be also ignited at atmospheric pressure, and since the late 1980s, an increasing interest has grown in the application of such plasmas (e.g., dielectric barrier discharge, corona, and atmospheric jet) to material processing (Kogelschatz 2003).

Cold plasmas can modify the surface of material by depositing thin films (plasma-enhanced chemical vapor deposition), by grafting specific chemical functionalities (plasma treatment), or by ablating materials (plasma etching).

Membranes can be processed by means of cold plasmas to activate the surface by introducing specific chemical groups such as hydroxyl, carboxyl, and amino moieties. This can be accomplished by feeding the plasma non-polymerizable gases/vapor such as O₂, H₂O, NH₃, and N₂/H₂. Alternatively, functionalized coatings can be deposited for the same purposes (e.g., acrylic acid or allylamine based). These treatments allow to tune surface properties of membranes, notably wettability and molecular adsorption, or to serve as anchor for specific biomolecules or catalysts (Favia et al. 2008; Fontananova et al. 2006; Roualdes et al. 2010).

Complexation–Ultrafiltration Process for Heavy Metal Removal from Effluents

Mohamed Abou El-Fetouh Barakat

Department of Environmental Sciences, Faculty of Meteorology, Environment and Arid Land Agriculture, King Abdulaziz University, Jeddah, Saudi Arabia

Central Metallurgical R & D Institute, Helwan, Cairo, Egypt

Metal rejection in aqueous solution containing Ni (II), Cu(II), and Cr(III) ions was evaluated (Barakat and Schmidt 2010) using complexation–ultrafiltration. The filtration experiments were performed with ultrafiltration membrane system, equipped with a polyethersulfone membrane (Figs. 1 and 2) with a 10,000 Da cutoff. The pressure was fixed at 1 bar with a permeate flow rate of 7.5 L/h, while CMC was used as a complexing agent. The process is pH dependent, and the metal rejection was more efficient at neutral and alkaline conditions than at acidic one. Metal rejection efficiency values were 97.6 %, 99.5 %, and

Complexation–Ultrafiltration Process for Heavy Metal Removal from Effluents, Fig. 2 Complexation–ultrafiltration system

99.1 % for Cu(II), Cr(III), and Ni(II) ions, respectively, at pH 7. The membrane had worked efficiently on a wide range of concentration up to 100 mg/l for both of Cu (II) and Cr (III) ions, while the Ni(II) ion rejection efficiency decreased to 57 %. The process is characterized by low energy requirements involved in the ultrafiltration, the very fast reaction kinetics, and the high selectivity for the metal ion separation.

Composite Membrane with Inorganic Fillers: Electrolyzer Application

Composite recast Nafion[®] membranes containing inorganic fillers have been primarily employed in fuel cells for high-temperature operation (Aricò et al. 1998) and self-humidification purposes (Watanabe et al. 1996). Composite membrane with inorganic fillers for electrolyzer application has been developed in order to extend the operating temperature range of polymer electrolyte membrane (PEM) electrolyzer and to reduce gas crossover effects (Antonucci et al. 2008).

Generally, Nafion[®] membrane is used as conducting polymer electrolyte in PEM electrolyzer systems. An increase of the operation temperature of an electrolyzer should enhance the oxygen evolution reaction rate that is the rate-determining step of this process allowing to obtain high current and high conversion efficiency. However, commercial Nafion membranes loose conductivity at temperature above 100 °C due to membrane dehydration. Perfluorosulfonic acid (PFSA) composite membranes containing hygroscopic ceramic oxide

fillers that require water for proton conduction appear suitable for this application especially in the light of the high operating pressure of PEM electrolyzers (up to 100 bars) that allows to maintain a good fraction of liquid water even at temperatures above 100 °C. The inorganic fillers enhance the water retention inside the composite membrane allowing to operate properly at high temperatures. A composite Nafion–SiO₂ membrane for SPE electrolyzers has shown promising properties for high-temperature operation allowing to achieve significantly higher

Composite Membrane with Inorganic Fillers: Electrolyser Application, Fig. 1 Polarization measurements for a PEM water electrolysis cell based on conventional Nafion 115 and composite PFSA–SiO₂ membrane at various temperature and 3.0 bar abs pressure

performances with respect to a bare commercial Nafion. This effect is mainly due to a significantly better water retention than the bare perfluorosulfonic membrane and lower gas crossover as a result by the increased tortuosity effect produced by the inorganic filler inside the membrane. The performance of the electrolyzer based on Nafion-SiO₂ membrane increased as a function of the temperature up to 120 °C and pressure. A maximum current density of about 2.1 A cm⁻² versus 0.7 A cm⁻² at 1.9 V, 120 °C, and 3 bar abs was recorded for the composite membrane compared to Nafion 115 (Fig. 1). An increase of electrical efficiency was recorded at low current densities for the high-temperature SPE electrolyzer compared to conventional membrane-based devices (Antonucci et al. 2008).

Composite Membrane with Inorganic Fillers: Fuel Cell Application

Antonino Salvatore Arico
CNR-ITAE Institute, Messina, Italy

Composite recast Nafion[®] membranes containing inorganic fillers have been employed in high-temperature (~150 °C) direct alcohol (Aricò et al. 1998) and H₂-air fuel cells (Watanabe et al. 1996). These composite membranes were

originally developed for reduced humidification operation in polymer electrolyte fuel cells (Watanabe et al. 1996) due to the enhanced water retention inside the membrane by the effect of the inorganic filler (Aricò et al. 1998). A further advantage of composite membranes relies in the barrier effect given by the inorganic filler for methanol cross over (Ren et al. 1996) which is of particular relevance at high temperature. It is well known that the physical adsorption of water by materials such as silica (one of the most used inorganic fillers) is mainly determined by their surface properties; similar considerations can be made for other hygroscopic inorganic oxides such as alumina. Functional groups on the surface of these oxides are believed to act as water coordination centers (Aricò et al. 2003). FTIR analysis of various silica materials suggests that oxygen surface functionalities play a prevailing role in the adsorption of water. The surface characteristics of an inorganic oxide can be modified by thermal treatments in inert or oxidizing atmosphere through reactions with strong inorganic acids (Aricò et al. 2003). Most of the works on composite membranes have addressed the technical aspects related to the use of these materials as electrolytes in high-temperature fuel cells. Accordingly, performance, conductivity, and stability characteristics have been investigated in-depth. Parallel work has been concerned with the investigation of relevant filler properties for application in composite membranes such as surface area analysis, surface chemistry studies, and surface acid-base investigations of the fillers. The conductivity of perfluorosulfonic acid (PFSA) composite membranes and fuel cell power density at high temperature have been found to be related to the characteristics of the water adsorbed on the filler particles. Inorganic fillers characterized by acidic properties undergo a strong interaction with water and enhance the DMFC performance at high temperature. Appropriate selection of the surface properties for the inorganic fillers thus allows to enhance proton conductivity and fuel cell performance and extends the operating temperature range of composite membranes (Aricò et al. 2003; Fig. 1).

Computational Fluid Dynamics (CFD) and Membranes

Philippe Moulin

Laboratoire de Mécanique, Modélisation et
Procédés Propres (M2P2-UMR 7340), Equipe
Procédés Membranaires (EPM), Aix Marseille
Université, AIX en PROVENCE, France

The increasing number of CFD membrane studies is clearly related to the recent developments in computer power and to the use of finer grid meshes in the vicinity of the membrane. Two approaches have been particularly considered: the comprehension of the hydrodynamics and of the mass transfer.

The hydrodynamics allows the increase of the shear stress near the wall or the transmembrane pressure thus allowing the enhancement of permeate flux and the membrane processes. CFD allows determining the hydrodynamics, i.e., the pressure and velocity fields, taking into account the geometry of the module and the membranes, the membrane permeability and compactness, as well as the operating entry values such as filtration or backwash pressures, filtration mode, and gravity. For example, it is possible to determine the pressure and velocity fields in (i) a hollow fiber module containing more than 40,000 fibers (small diameter ($d_i = 0.93$ mm) and large flow rate ($50 \text{ m}^3 \cdot \text{h}^{-1}$) or in (ii) ceramic multichannel membranes or module to obtain information about the wall shear stress distribution at the surface of the membrane. The study of hydrodynamics reveals the optimum operating conditions and the most suitable geometry characteristics to determine a compromise between membrane area, channel (geometry and number), and energy consumption to optimize membrane processes. A large number of studies relate to the diphasic flows, to the turbulence promoters, and to the geometries of membranes capable of generating secondary flows. Usually a good agreement is obtained between CFD and experimental data obtained for the transfer of solvent. Some recent studies consider turbulent flows and the significant number of

turbulence models in numerical simulations, and their comparison with experimental results in the case of membrane processes is not excellent, which limits the use of CFD in turbulent regime.

Fouling remains a major problem in membrane processes: this phenomenon limits the process efficiency and is difficult to predict and anticipate. These difficulties are linked to the complexity of this phenomenon which implies different interdependent mechanisms occurring at pore scale. The relative importance of each fouling mechanism has been determined according to the particle size, the pore size, and the surface density of pores. By CFD progress it is now possible (a) to pursue the description of the different fouling mechanisms by integrating the complexity of the real membrane structure in the numerical simulation and (b) to simulate different kinds of experimental deposit structure. The limitation is the membrane reconstruction technique limiting this description at the MF and UF membranes. The filtration in a cylindrical pore (i.e., microchannels) can be simulated for different sizes of particles or pores, tortuosities, and hydrodynamic conditions. For these CFD studies, the difficulties are to well describe particle/particle colloidal interactions and resuspension of particles after capture.

Thus, CFD is without any doubt an important tool for understanding mass transfer in membrane processes, and opportunities for the development of new membrane geometries are numerous.

Computer-Aided Methods and Tools

Giorgio De Luca

Institute on Membrane Technology, National
Research Council, ITM-CNR, Rende, Italy

Computational methods can be divided into approaches using adjustable or empirical parameters and those which do not use them. Concerning the first methods, several procedures have been developed for the optimization of the adjustable parameters. For example, design of experiments is

Computer-Aided Methods and Tools, Fig. 1 Computational methods and achievable properties

an approach defining the minimum number of experiments required to obtain the fitting parameters. Instead, in the *ab initio* methods, these quantities are obtained by direct experimental measurements or from other simulations carried out in smaller time-space scale (Steinhauser 2008), until the sub-nanometer scale is reached.

The choice of the computational approaches strictly depend on the properties to be studied. Figure 1 shows the various computational methods and properties that can be obtained.

Binding energies, molecular electrostatic properties must be evaluated by quantum mechanics (QM) approaches (Veszprémi and Fehér 1999). These generally require significant computational resources, although the development of parallel supercomputers and efficient algorithms have allowed to carry out QM calculations unthinkable few years ago. The quantities, obtained at QM level, can be used in subsequent molecular dynamics (MD), Monte Carlo (MC), or semiempirical calculations to describe properties related to a huge number of molecules and atoms, like polymers. MD methodologies are based on the simultaneous solution of Newton's equation of motion referred to the atoms of the physical system (Allen and Tildesley 2003). The potential energy surface (interaction potential), also called

force field (FF), used in the MD simulations is defined by QM or parameterized over measurements. The temperature, volume, pressure, and number of particles define the statistical ensemble in which the MD can be performed. The classic MC method is generally based on the von Neumann, Metropolis, and Ulam algorithm (Metropolis and Ulam 1949; Wood 1986). Later, the method has grown to the point where it leads to several methods all belonging to the MC family. In the grand canonical MC ensemble, the simulations are performed at chemical potential, volume, and temperature constant, whereas the number of molecules varies. The potential surface energy is always defined by means of a specific FF. Interesting MC approaches are based on the quantum MC methodology. The semiempirical methods use Hamiltonians to describe the system, but some contributions of these operators are obtained empirically (Clementi and Corongiu 1995). These approaches allow to evaluate the target properties more quickly than the QM methods. In Table 1, the illustrated computational methods are summarized with their advantages and disadvantages.

The information provided by smaller scales can be utilized in mesoscale calculations: coarse grain MD or Lattice Boltzmann (LB) (Swift

Computer-Aided Methods and Tools,
Table 1 Advantages and disadvantages of some computational methods

Method	Advantages	Disadvantages
Molecular mechanics and Monte Carlo dynamics	Systems of thousands of atoms, low computational costs	Experimental data or values from quantum mechanics, absence of bond breaking/forming. Noncovalent bonds are not well described, less general
Semiempirical	Less computational demand than quantum mechanics approaches, systems of hundreds of atoms	Experimental data or values from quantum mechanics, less general
Ab initio, density functional theory quantum mechanics	Do not depend on experimental data, useful for a broad range of molecules without available experimental data, general	Computationally very expensive Small systems

et al. 1996). In particular, LB is a powerful method for simulating fluid confined in microsystems, as may be precisely a membrane. This method allows to solve the Navier-Stokes equations in a simple way and with a notable reduction of computational time. LB allows an easy description of the interfaces and especially without the use of adjustable parameters as made by the conventional finite elements methods (FEM). Finally, the description of the properties of macrosystems can be carried out using methods based on classic mechanics or dynamics. The differential equations describing these physical systems are evaluated numerically by means of FEM or finite volume procedures (De Luca et al. 2014). There is a notable number of codes implemented for each method just described. These are divided into programs in which a single methodology is implemented or those in which several methods, radically different, can be found. Therefore, it is possible to find codes in which only QM (based on different theories) or MD are implemented

separately and others in which both the methodologies are present. Particular attention should be given to parallel algorithms since parallel supercomputers allow the use of huge number of processors (or computers interconnected by the net). These possibilities allow to perform complex calculations in short computational time.

Computer-Aided Models

Giorgio De Luca

Institute on Membrane Technology, National Research Council, ITM-CNR, Rende, Italy

Models can be divided into mathematical and structural (chemical models), both connected to each other. Mathematical models and procedures can be numerical algorithms, in which each single step is simple arithmetic and logical relations, or they can be defined by analytical relationships, regardless of how they are evaluated. In either case, mathematical models and procedures are the result of some assumptions or approximations

Computer-Aided Models, Fig. 1 CNT structural models

based on structural or chemical models (Allen and Tildesley 2003; De Luca et al. 2006, 2008). For example, the description of a droplet formation during membrane emulsification by means of analytical force-balance relationships requires some approximations about the droplet shape and its evolution along the membrane membrane pore. Moreover, the shape of the membrane pores should be also modeled. Therefore, any mathematical model can be correlated with structural or chemical models. By using computational procedures, starting from quantum mechanical calculations, molecular dynamics (MD) or Monte Carlo (MC), in fact particular attention should be paid to the molecular (chemical) models. Molecular models are closely dependent on the target properties to be assessed as well as on the computational time required to get these properties. Computational time, in turn, depends on the level of theory used, that is, the mathematical approaches.

For example, at the moment, quantum mechanical methods are not applicable to optimize the geometry of macromolecules as polymers or systems containing thousands of atoms like biological systems. Molecular dynamics methodologies or coarse grain Monte Carlo can be used in these cases. However, molecular dynamics approaches cannot be used to study systems in which the breaking and formation of bonds or noncovalent bonds are decisive. Thus, in the latter case, the choice of a chemical model of macromolecules is

crucial. These structural models, also called analogues, inevitably lead to neglect some aspects; nevertheless in some cases these may be irrelevant if the choice of the analogues is done correctly. In fact, albeit molecular models certainly introduce approximations in the evaluation of the macromolecular or biological proprieties, some functions of these only depend on a limited part of the whole structures. Thus, chemical models can mimic very well the function of complex systems (Gademann et al. 2007; Zürcher et al. 2006; Saxer et al. 2010). Some examples, concerning models of carbon nanotubes (CNT), have been presented in Fig. 1. In summary, mathematical models, computational methods, and structural (chemical) models carefully tune as a function of the type of calculation which is required to be done. Huge literature exists about studies on any kind of chemical models (*periodic surfaces, slabs, or clusters*) and correlated computational procedures (*periodic calculations, embedded clusters, and quantum mechanics/molecular mechanics methods, etc.*).

Concentration Polarization Coefficient (CPC)

Alessio Caravella

National Institute of Advanced Industrial Science and Technology – Research Institute for Innovation in Sustainable Chemistry, ISC-AIST, Tsukuba, Ibaraki, Japan

Concentration polarization coefficient (indicated in the literature as *PC* or *CPC*). The

concentration polarization coefficient is a measure of the concentration polarization extent in a membrane-aided separation system. In general, the concentration polarization coefficient indicates the degree of permeation driving force lost with respect to the total driving force between the bulks of the fluid phase of feed and permeation side (Fig. 1).

In the open literature, it is possible to find several different definitions of *CPC* (see Table 1 for the most used), leading to different quantifications of this phenomenon. All definitions refer to a key species permeating through the membrane. In particular, for constant total pressure in feed and permeate side, the definitions of Wijmann et al. (1996), Yeom et al. (2002), and Zhao et al. (2008), who used a coefficient per each membrane side in order to take into account also the polarization in the downstream side, are in fact coincident. Based on these definitions, *CPC* tends to zero for increasing polarization, going toward the unity in the opposite situation (no polarization).

On the contrary, Wang et al. (2002) defined the *CPC* in such a way that it be close to the unity when concentration polarization is significant. A more useful definition is provided by Haraya et al. (1987) and Takaba and Nakao (2005), who considered a unique coefficient for accounting the polarization on both the membrane sides (Table 1).

Concentration Polarization Coefficient (CPC), Fig. 1

Schematic representation of the driving force (*DF*) drops along the permeation direction in case of hydrogen permeation through Pd-based membranes. The *solid* and *dashed* lines indicate the forward and backward permeation case, respectively. The profiles are expressed in terms of equivalent partial pressure (Adapted from Caravella et al. (2009))

c concentration, *x* molar fraction, *N_i* actual flux of the *i*th species, *N_i*⁰ flux of the *i*-th species without concentration polarization

In order to link the polarization effect to the selectivity of a membrane, Zhang et al. (2006) used the permeating fluxes in the *CPC* definition without specifying any explicit form of driving force.

In general, for *CPC* to provide an appropriate quantification of the driving force loss, it is advisable to define it using the driving force characteristic of the permeation mechanism that takes place. By doing this for hydrogen permeation through Pd-based membranes, Caravella et al. (2009) defined the *CPC* using the Sieverts characteristic driving force, as indicated in Table 1. In this case, the *CPC* is equal to zero in systems without polarization, tending to the unity for maximum polarization (external mass transfer controlling the overall permeation process).

Concentration Polarization in Gas Separation

Alessio Caravella
National Institute of Advanced Industrial Science and Technology – Research Institute for Innovation in Sustainable Chemistry, ISC-AIST, Tsukuba, Ibaraki, Japan

In a separation process using membranes, *concentration polarization* (see also *bed-to-wall mass transfer limitations*) consists in decrease of the

Concentration Polarization in Gas Separation,

Fig. 1 Sketch of the concentration polarization phenomenon. The presence of the less-permeating species (b) generate a resistance to the flux of the more permeable species (a)

permeation driving force of more permeable species through the membrane because of the presence of less permeable species, which act as an additional resistance to permeating flux. The scheme reported in Fig. 1 provides the physical situation leading to concentration polarization. In particular, the species B is pushed toward the membrane surface by the effect of the flux of the species A. In these conditions, there is also a split in the respective concentration of the two species, which means that the concentration of the more permeable species A tends to be higher in the bulk of the feed fluid phase, while at the same time, the concentration of the species B tends to be higher in the proximity of the surface. From this point of view, it is possible to say that the concentration polarizes, analogously to what occurs in electrical polarization, where electric charges accumulate toward the respective electrodes.

In practice, concentration polarization occurs in every membrane-aided device and cannot be completely removed, but rather minimized. Furthermore, the higher the membrane selectivity (or separation factor), the higher the effect of concentration polarization, because the removal of the non-permeating species from membrane surface becomes more difficult.

Historically speaking, the first field where causes and effects of concentration polarization were analyzed in detail (since the beginning of the 1960s) was the liquid separation processes through membranes – such as ultrafiltration and

reverse osmosis. On the contrary, in the same period, concentration polarization had been considered negligible in gas separation, both because of the low the membrane performance in terms of permeation flux and because gases have diffusivity of four to five orders of magnitude higher than liquids (He et al. 1999).

However, the progresses obtained in the last decades in the field of membrane preparation for gas separation allowed increasing significantly the transmembrane flux of the key species to separate. The higher permeation flux causes the less-permeating species to concentrate (“polarize”) around the membrane surface, generating a phenomenon similar to the electrical polarization, from whose analogy concentration polarization takes its name.

In these conditions, the influence of the selective layer decreases with respect to the resistance of the external mass transfer can affect seriously the membrane performances up to become one of the slowest elementary steps of the overall permeation process (Caravella et al. 2009).

Concentration Profile

Alessio Caravella

National Institute of Advanced Industrial Science and Technology – Research Institute for Innovation in Sustainable Chemistry, ISC-AIST, Tsukuba, Ibaraki, Japan

The concentration of a chemical species that is present in a certain volume of space V with a certain amount of mass is defined as the ratio between this amount of mass and the volume V . It can be expressed in terms of moles (i.e., molar concentration c_i [mol m⁻³], Eq. 1) or mass (mass concentration or mass density ρ_i [kg m⁻³], Eq. 2).

$$c_i = \frac{n_i}{V} \quad (1)$$

$$\rho_i = \frac{m_i}{V} \quad (2)$$

In general, a (nonconstant) concentration profile can be established because of the presence of sources/sinks (distributed and or concentrated) of momentum, mass, and/or energy in some locations within the physical domain considered.

In *membrane technology*, researchers are mostly interested in the evaluation of concentration profiles both through membrane and in membrane device, including the fluid phase in feed and permeate side. As for the former, the transmembrane flux J_i [mol s⁻¹ m⁻²] and, thus, the concentration profile of the i th species through membranes are promoted by a difference of its chemical potential μ_i [J mol⁻¹] between feed and permeate side (Eq. 3) (Wijmans and Baker 1995; Bachorczyk et al. 2003; Hara et al. 2012).

$$J_i = -L_i \frac{d\mu_i}{dy} = -c_i B_i \frac{d\mu_i}{dy} \quad (3)$$

In Eq. 3, L_i is a proportionality factor (not generally constant), B_i is the mobility (i.e., a measure of the aptitude of the i th species to pass through membrane), and y indicates the permeation direction (normal to membrane surface).

If the permeation driving force is mainly generated by partial concentration and pressure, the

permeating flux can be mathematically expressed as follows:

$$\frac{d\mu_i}{dy} = RT \frac{d\ln(\gamma_i x_i)}{dy} + \bar{v}_i \frac{dP}{dy} \quad (4)$$

where P [Pa] is the total pressure, γ_i is the activity coefficient linking the molar fraction x_i [mol mol⁻¹] to the activity a_i [–], and $\bar{v}_i$ [m³ mol⁻¹] is the partial molar volume. Based on the different permeation models to apply to different membrane types (dense or porous), different concentration profiles are established through the membrane.

The most common permeation models for dense and porous membranes are the solution-diffusion model and the pore-flow model. The former assumes that the pressure within a membrane is uniform and that the chemical potential gradient across the membrane is expressed only as a concentration gradient. The latter assumes that the concentrations of solvent and solute within a membrane are uniform and that the chemical potential gradient across the membrane is expressed only as a pressure gradient.

Constant-Volume Diafiltration

Zoltán Kovács

Department of Food Engineering, Institute of Bioengineering and Process Engineering, Szent Istvan University, Budapest, Hungary

Constant-volume diafiltration (also called constant-volume dilution mode) is a batch

diafiltration process for separating microsolute from macrosolutes, in which the volume of the process liquor is kept constant during filtration by continuously adding a diluant into the feed tank at a rate equal to the permeation rate. The schematic representation of its configuration is shown in Fig. 1. The constant tank volume can be maintained by the use of a ball float valve or by means of liquid level controller (Beaton and Klinkowski 1983). As filtration progresses, the concentration of membrane-permeating microsolute in the feed tank continuously decreases, while that of the macrosolutes remains ideally unchanged (or close to constant in case of incomplete rejection).

Note that some literature sources misleadingly refer to “constant-volume diafiltration” as “continuous diafiltration.” Although the addition of diluant is performed in a continuous manner, constant-volume diafiltration should not be considered as a continuous process. It is a true batch process. It is advised, however, to use the term “constant-volume dilution mode” which is less common in the literature. The term “dilution mode” reveals that this technique is actually an operational mode of a membrane filtration process in which the process liquor is diluted with pure solvent.

Depending on the technological goal, either the permeate or the retentate represents the phase of primary economic importance. Thus, the product of the operation is either formed in the feed tank as a purified mixture of macrosolutes or collected in the permeate tank where the microsolute is accumulated. Both treatments pose a dynamic modeling problem. A mass balance on component

i in the feed tank gives the following initial value problem for its concentration $c_{f,i}(t)$:

$$\begin{cases} \frac{dc_{f,i}}{dt}(t) = \frac{c_{f,i}(t)q(t)[R_i(t) - 1]}{V_f} \\ [3 \text{ mm}]c_{f,i}(0) = c_{f,i}^0 \end{cases}$$

where $q(t)$ and $R_i(t)$ are the permeate flow and the solute rejection that are subject to change during operation. The constants V_f and $c_{f,i}^0$ denote the volume of the feed tank and the initial feed concentration of component i . The equation describes the evolution in time of the feed concentration $c_{f,i}(t)$ assuming that the diluant consists of no component i and the feed tank is well mixed.

In many applications, the flux and the rejections are concentration-(inter)dependent quantities (Kovács et al. 2009) and may vary with operating conditions such as temperature, applied pressure, and hydrodynamics. In such cases, no closed form solution of the set of resulting complex differential algebraic equations exists; thus, numerical techniques are required to solve the model equations. Under the simple assumptions of constant permeate flow and rejections, however, the problem can be reduced to the following algebraic expression:

$$\ln\left(\frac{c_{f,i}(t)}{c_{f,i}(0)}\right) = D(R_i - 1)\% \quad \text{for } i = 1, 2, N$$

where D is the diafiltration factor (also called diavolume) that is defined as the ratio of applied volume of diluant to feed volume. For applications where the objective is to reduce the microsolite concentration by a fixed amount, the

Constant-Volume Diafiltration,

Fig. 1 Schematic representation of constant-volume diafiltration settings

Constant-Volume Diafiltration,

Fig. 2 Dependence of microsolute removal on applied diavolumes in constant-volume diafiltration

necessary diavolumes can be determined based on Eq.2 as illustrated in Fig. 2.

In practice, constant-volume dilution mode is frequently preceded and/or followed by batch concentration operational steps in order to reduce the initial feed volume to a desired level and, thus, to concentrate the macrosolutes (for further details, see entry on “traditional diafiltration”).

Contactor-Type Catalytic Membrane Reactor

Juergen Caro
Institute of Physical Chemistry and
Electrochemistry, Leibniz University, Hannover,
Germany

Synonyms

Catalytic diffuser; Pore-through-flow catalytic membrane

The term “catalytic membrane contactor” refers to a device in which a membrane containing a catalytically active phase is used to provide the reaction zone for conversion of one or more reactants from one or more fluid phases (Dittmeyer and Caro 2008). The membrane not always has a separation function, it provides the surface-rich reaction zone for a gas-liquid, but also for a gas-gas and a liquid-liquid reaction. Applications of membranes with built-in catalysts for gas-liquid reactions have been also reviewed in Dittmeyer et al. (2004).

The catalytic diffuser concept can be utilized for solid-catalyzed gas/liquid reactions in various ways. If the membrane is not wetted, the operation principle is similar to that of a membrane contactor. The gas is on the support side, and the liquid is pumped through the shell side. The gaseous reactants enter the liquid phase at the gas/liquid contact plane which is established at the pore mouth towards the external membrane surface. The catalyst is deposited on this surface and gets in contact with the reactants. On the contrary, if the membrane is wetted the gas and not the liquid is at overpressure as described in Dittmeyer and Caro (2008).

Gas-liquid contactors without catalytic function can be used in gas adsorption. Examples are carbon dioxide removal from gas mixtures using monoethanolamine (Simons et al. 2009) or ionic

liquids (Albo et al. 2010) as carbon dioxide absorbing solutions.

For liquid-liquid and gas-gas catalytic membrane contactors, see Dittmeyer and Caro (2008) (Fig. 1).

Catalytic diffuser with wettable membrane: The active material is placed solely into the surface layer of an asymmetric membrane. By applying overpressure on the gas side, above the bubble point pressure of the intermediate layer but below that of the surface layer, the gas/liquid contacting plane is established inside the membrane close to the surface layer. In this way, a short diffusion path for the liquid and for the gas reactant is achieved (after Dittmeyer and Caro (2008)).

Contactortype Catalytic Membrane Reactor, Fig. 1 Catalytic diffuser with wettable membrane as an example for a Contactortype Catalytic Membrane Reactor for a solid-catalyzed gas-liquid reaction. By applying overpressure on the gas side, the gas-liquid contacting plane is established inside the membrane close to the surface. In this way, a short diffusion path for the liquid and for the gas is achieved. Continuous Diafiltration: Cocurrent and Countercurrent Modes

Zoltán Kovács

Department of Food Engineering, Institute of Bioengineering and Process Engineering, Szent Istvan University, Budapest, Hungary

Continuous diafiltration is a type of diafiltration that accomplishes the selective separation of multiple solutes in a continuous fashion by mixing the feed stream with diluant and pumping it across the membrane with permeate and retentate being removed. The role of diluant addition is to facilitate the separation of membrane-permeating microsolute from the retained macrosolute. This strategy is generally applicable to a variety of microfiltration, ultrafiltration, nanofiltration, and reverse osmosis systems and commonly employed in plants that require large throughputs. Its simplest configuration, known as single-pass diafiltration, is schematically shown in Fig. 1a. Continuous diafiltration, as opposed to batch diafiltration, realizes a steady-state separation in which the product (i.e., the final retentate) is not formed in the feed vessel as filtration progresses, but being continuously withdrawn from the system during the entire course of filtration. In practice, continuous processing employs feed-and-bleed configuration

Continuous Diafiltration: Cocurrent and Countercurrent Modes, Fig. 1 (a) Single-pass continuous diafiltration and (b) continuous diafiltration with partial retentate recycle (feed and bleed)

Continuous Diafiltration: Cocurrent and Countercurrent Modes, Fig. 2 Simplified flow diagram of multistage cocurrent (*top*) and countercurrent (*bottom*) continuous diafiltration

to enhance separation as shown in Fig. 1b. Here, the retentate is split, and a portion of it is recycled back to the cartridge inlet.

Large-scale continuous diafiltration systems operate in multistage arrangement in which a portion of the retentate generated in one stage is used as the feed to the next. These systems can reach higher system recoveries, without exceeding the single element recovery limits. Each stage may consist of several membrane elements

arranged in feed-and-bleed configuration. The two basic concepts of multistage arrangement are the cocurrent (also called crosscurrent) and the countercurrent configurations (Dutr  and Tr g rdh 1994). The former applies fresh diluant at each stage, while the latter uses recycled permeate as diluant as shown in Fig. 2.

Continuous membrane plants are usually designed for both concentration and fractionation purposes. To achieve the twin objectives

of concentrating and purifying a multicomponent feed, the combined application of both concentration mode and diafiltration mode operation is required. Traditional continuous membrane systems consist of a number of stages in series in which consecutive stages are assigned to perform the tasks of pre-concentration, diafiltration, and final concentration (Madsen 2001). Many design variations exist in practice that are primarily achieved by the manipulation of the arrangement of stages within the plant, the number of stages and filtration areas assigned to the various tasks, the amount and the place of fresh diluant addition in the process train, the introduction of bypasses and manifolds, the alteration of permeate recycle ratios, and the appointment of the stages in which permeate is withdrawn from and recycled to (Morison and She 2003, Yee et al. 2007; Mohanty and Ghosh 2008). The selection of optimal diafiltration strategy in continuous processing is very case specific. In general, a reduced consumption of fresh diluant but a larger membrane area is required for the countercurrent approach (i.e., reintroduction of permeate as diluant in the process train) as compared to cocurrent process if the same degree of purification is to be attained (Lipnizki et al. 2002).

Continuous Electrodeionization

Karel Bouzek

Faculty of Chemical Technology, University of Chemistry and Technology Prague, Technick   5, Prague 6, Czech Republic

Continuous electrodeionization is an alternative term for electrodeionization; however, it emphasizes the fact that, in contrast to classical deionization by ionic exchange, this process is continuous.

Continuous Membrane Fermentor (CMF)

► [Cell Recycle Membrane Fermentor](#)

Continuous Stirred Tank Membrane Reactor (CST-MR)

Giuseppe Barbieri

Institute on Membrane Technology, National Research Council, ITM-CNR, Rende, Italy

Before introducing the continuous stirred tank membrane reactor (CST-MR), it is useful/helpful to report about the continuous stirred tank reactor (CSTR).

The continuous stirred tank reactor (CSTR) is an ideal reactor model assuming perfect mixing, with no spatial gradients of any variable such as species concentration, temperature, pressure,

Continuous Stirred Tank Membrane Reactor (CST-MR),

Fig. 1 Continuous stirred tank reactor (CSTR) scheme

etc. The effect of the perfect mixing is the same value for, e.g., concentration, temperature, etc., in any point of the whole reactor volume; and their values are equal to those of the stream exiting the reactor. In addition, the reaction rate has the same value in any point of the reactor. Therefore, this reactor model operating at the lowest reactant concentration and the highest product concentration results in the lowest reaction rate. However, an important effect of perfect mixing is an easy temperature and reaction rate control, which results quite simply. Figure 1 shows a CSTR scheme.

The generic balance equation on the reactor volume will be:

$$\begin{aligned} \text{Inlet} - \text{Outlet} + \text{Generation} \\ = \text{Accumulation} \end{aligned} \quad (1)$$

The mass balance for the component i -th considering a single reaction will be:

$$F_i^{\text{Inlet}} - F_i^{\text{Outlet}} + \sum_{j=1}^{N_{\text{reactions}}} v_{i,j} r_j V_{\text{CSTR}} = \frac{dN_i}{dt} \quad (2)$$

Mass balances provide a set of ordinary differential equations (ODEs), in which the number of moles of component i -th is time dependent. In Eq. 2, F_i^{Inlet} and F_i^{Outlet} are, respectively, the inlet and outlet molar flow of the component i -th, r_i is the reaction rate, N_i is the number of moles, and V is the reactor/reaction volume.

Continuous Stirred Tank Membrane Reactor (CST-MR), Fig. 2 Continuous stirred tank membrane reactor (CST-MR)

In steady-state condition, the mass balance equations fall into algebraic equations:

$$F_i^{\text{Inlet}} - F_i^{\text{Outlet}} + \sum_{j=1}^{N_{\text{reactions}}} v_{i,j} r_j V_{\text{CSTR}} = 0 \quad (3)$$

Equation 3 provides the design equation Eq. 4 for a CSTR in steady-state conditions:

$$\begin{aligned} V_{\text{CSTR}}^{\text{Reaction}} = \frac{F_i^{\text{Inlet}} - F_i^{\text{Outlet}}}{N_{\text{reactions}}} \\ - \sum_{j=1} v_{i,j} r_j \end{aligned} \quad (4)$$

An increase in reaction rate r_i causes a reduction of reactor volume (Eq. 4). The design equation

also provides the reactor volume necessary for obtaining the exit flow rate F_i^{Outlet} , from the feed conditions F_i^{Inlet} , and the reaction rate knowledge.

The energy balance, coupled to mass balance, is given by Eq. 5:

$$\text{Conversion} = \frac{C_p(T^{\text{Outlet}} - T^{\text{Inlet}}) - UA(T^{\text{Outlet}} - T^{\text{External}})}{-\Delta H_{\text{Reaction}}} \quad (5)$$

where C_p is the mean heat capacity, T^{External} is the external temperature, U is the overall heat transfer coefficient, A is the heat exchange area, and ΔH is the enthalpy of the chemical reaction.

This equipment is very commonly used in continuous industrial processes as well as in the plug flow reactor. For reactions of greater than zero order, CSTR always requires a volume larger than that of a plug flow reactor to achieve the same conversion; this is owing to the lower reactant concentrations, as said, at which it operates. Therefore, the use of CSTR is recommended when the desired reaction rate is smaller than that of the side reaction one in order to limit by-product formation.

CST Membrane Reactor

A membrane reactor is a device that combines in one unit a chemical reaction with selective product separation by means of a permselective membrane. The selective removal of products from the reaction side to the permeate side also provides an increase, e.g., of the reaction rate and equilibrium conversion (Fig. 2).

A continuous stirred tank membrane reactor [1, 2] (CST-MR) is a device characterized (1) in addition to the same properties described above

for the CSTR (perfect mixing that has no spatial gradients of species concentration, temperature, pressure, etc.) on both reaction and separation sides (2) by the selective removal of reaction product by the membrane allowing improved performance (see later on) with respect to a CSTR.

The generic mass balance (Eq. 1) is still valid and has to be written down for both reaction and permeation even though another term has to be included: the one taking into account the permeation through the membrane. Therefore, Eqs. 6 and 7 include the permeating flow rate ($A^{\text{Membrane}} J^{\text{Permeating}}$, the product of the membrane area and permeating flux). This term is negative (being mass leaving the reaction volume) on the retentate side and positive (entering the permeation volume) on the permeate one.

Reaction side:

$$\begin{aligned} F_i^{\text{Feed}} - F_i^{\text{Retentate}} - A^{\text{Membrane}} J_i^{\text{Permeating}} \\ + \sum_{j=1}^{N_{\text{reactions}}} v_{i,j} r_j V_{\text{CST-MR}}^{\text{Reaction}} \\ = \frac{dN_i^{\text{Retentate}}}{dt} \end{aligned} \quad (6)$$

Permeation side:

$$\begin{aligned} F_i^{\text{Sweep}} - F_i^{\text{Permeate}} + A^{\text{Membrane}} J_i^{\text{Permeating}} \\ = \frac{dN_i^{\text{Permeate}}}{dt} \end{aligned} \quad (7)$$

The mass balance equations for steady state have an algebraic form:

Reaction side:

$$\begin{aligned} F_i^{\text{Feed}} - F_i^{\text{Retentate}} - A^{\text{Membrane}} J_i^{\text{Permeating}} + \sum_{j=1}^{N_{\text{reactions}}} v_{i,j} r_j V_{\text{CST-MR}}^{\text{Reaction}} = 0 \\ V_{\text{CST-MR}}^{\text{Reaction}} = \frac{(F_i^{\text{Feed}} - F_i^{\text{Retentate}}) - A^{\text{Membrane}} J_i^{\text{Permeating}}}{\sum_{j=1}^{N_{\text{reactions}}} v_{i,j} r_j} \end{aligned} \quad (8)$$

Permeation side:

$$F_i^{\text{Sweep}} - F_i^{\text{Permeate}} + A^{\text{Membrane}} J_i^{\text{Permeating}} = 0$$

$$A^{\text{Membrane}} J_i^{\text{Permeating}} = F_i^{\text{Permeate}} - F_i^{\text{Sweep}} \quad (9)$$

Equation 8 also identifies the reaction volume. It results lower than the CSTR reaction volume owing to the permeation through the membrane.

Therefore, a continuous stirred tank membrane reactor (CST-MR) has a higher performance of a continuous stirred tank reactor (CSTR), specifically, for the following points:

1. Higher conversion owing to the selective permeation through the membrane
2. Higher reaction rate owing to the lower concentration of the products removed by the selective membrane
3. Lower reaction volume at the same productivity owing to the species permeation

Controlled Delivery

Sacide Alsoy Altinkaya
Department of Chemical Engineering, Izmir
Institute of Technology, Urla, Izmir, Turkey

The benefit of a drug can be enhanced when controlled delivery of a drug to a targeted tissue becomes possible. After release, the drug enters the systemic circulation and distributes according to its relative affinities to all tissues, and only a

small fraction of the drug is delivered to the target site. Accumulation in tissues not associated with drug causes side effects. Controlled delivery to the target tissue eliminates side effects and allows to reduce drug dosing to reach the desired effect. The need for controlled targeted delivery is obvious in chemotherapy, for example, where painful side effects of the drugs on healthy cells can be eliminated by directly delivering the drug to the target cells. Other examples include drug delivery to the eye, lung, brain, and coronary arteries and release of growth and angiogenesis factors from surgically implanted tissue-engineered constructs.

The eye cavity is used to deliver antibiotics and drugs. Ophthalmic inserts made from soluble, insoluble, and bioerodible polymers are currently available. Insoluble inserts can be categorized as diffusional, osmotic, and contact lens. Polyvinyl alcohol, hydroxypropylcellulose, polyvinylpyrrolidone, and hyaluronic acid are commonly used for constructing degradable inserts, while nondegradable inserts are manufactured from ethylene-vinyl acetate copolymers and styrene-isoprene-styrene block copolymers. The contact lenses are not only used for correcting vision but also act as potential drug delivery device by presoaking them in drug solutions. Conventional eye drops are not efficient since most of it is lost due to overflow. To increase drug retention in the cavity and bioavailability, drug delivery product *Ocusert*[®] was developed. In this system, a reservoir filled with a saturated concentration of drug was placed between two membranes that can control release of drug by the partition/diffusion mechanism. This product was placed under the lower eyelid and released drug at constant rate into the tear fluid for up to 1 week. Another commercial product, *Lacrisert*[®] is a soluble insert used for the treatment of dry eye syndrome. The device is composed of hydroxypropyl cellulose and slowly dissolves over 6–8 h to stabilize and thicken the tear film.

In addition to the eye, inserts are also used for targeted controlled delivery of drugs to various tissues. *ATRIDOX*[™] is an FDA-approved product designed for the treatment of periodontal disease. Upon injection into the periodontal cavity, drug delivery depot is formed and delivers the

antibiotic to the cavity. *DUROS*[®] implants are nondegradable, osmotically driven systems and used for the delivery of small drugs, peptides, proteins, and DNA for up to 1 year. *Viadur*[®] is another commercial implant used for treatment of advanced prostate cancer.

Drug-eluting stents were developed to prevent restenosis or reclosing of coronary arteries. In these systems, the implantable metal stents are coated with small amounts of anti-inflammatory and antiproliferative drugs that are released directly into the arterial tissue by dissolution, partitioning, and diffusion. The release rate is influenced by the thickness of the coating, type of the coating material, and diffusivity and solubility of drug in the coating material.

Nanocarriers are alternative systems for targeted controlled drug delivery since they are less cleared than free drugs and they may also have favorable distribution properties into target tissues. Targeting ligands can be incorporated into the nanoparticles, and they permit particles to bind specific cells and promote the cell uptake and release of drug into the cells. Drug-loaded nanoparticles can easily reach to target tumor tissues since tumors have leaky capillaries that permit the passage of nanoparticulates. Microemulsions, liposomes, dendrimers, block polymer micelles, and solid lipid and polymer nanoparticles are typical examples of nanocarriers.

Controlled Drug Release

Sacide Alsoy Altinkaya
Department of Chemical Engineering, Izmir
Institute of Technology, Urla, Izmir, Turkey

Controlled drug release is defined as delivery of a drug to a specific site, in specific time and release pattern. Controlled drug release eliminates over- or underdosing, maintains drug levels in desired range, needs less dosing, prevents side effects, and increases patient compliance. Most of the commercially available systems for controlled release of drugs rely on membranes where drug release is generally controlled by (1) osmotic pumping or

(2) solution–diffusion mechanism. Pills, implants, and patches are commonly used dosage forms to deliver drugs where drug release is controlled by diffusion through a rate-limiting membrane. Pills are prepared by pressing the drug into a tablet and then coating with a water-insoluble or water-soluble polymeric membrane, such as hydroxypropyl methylcellulose, ethylcellulose, povidone, or polyethylene glycol. Tablets are also coated with a membrane to protect drugs against decomposition in the acid environment of the stomach. Commonly used polymers for this purpose are cellulose acetate trimellitate (CAT), hydroxypropylmethylcellulose phthalate (HPMCP), polyvinyl acetate phthalate (PVAP), and cellulose acetate phthalate (CAP). Implants are used to deliver drug at a particular site and contain drug in liquid or powder form in a reservoir surrounded by a semipermeable membrane to allow slow release of the drug. The membrane can be made from a degradable or nondegradable polymer, and the release is controlled by rate of diffusion and degradation. Patches are typical membrane-controlled reservoir systems and frequently used for controlled drug delivery. In ocular patches, a drug is enclosed by two release-controlling polymer membranes, and through diffusion, drug is delivered to the target area. Transdermal patches are used to deliver drugs with low solubility since the skin has a large surface area. The simplest patch consists of a drug-containing reservoir placed between an impermeable backing layer and a membrane. The total resistance to drug permeation is controlled by sum of the resistances in the membrane and the skin. In the case of passive drug transport where the drug concentration difference between the patch and the skin is main driving force, the release rate of the drug may vary significantly from patient to patient due to strong variations in skin permeability. In order to provide an effective rate control and to ensure that drug delivery does not depend on patient or patch position, the permeability of membrane should be less than that of the skin, i.e., the release rate should be controlled by the membrane. To expand the spectrum of transdermally deliverable drugs, chemical permeation enhancers, microneedles, ultrasound, heat, or short- or high-

voltage bursts of electricity are temporarily applied to the skin to disrupt its barrier function. Alternatively, drugs can be delivered by iontophoresis, in which small amounts of electrical current are applied through the skin to allow delivery of charged drug molecules into the body. The device consists of two patches: one of them contains a drug reservoir, while the other patch contains reference electrolyte or gel. The drug placed in the patch electrode which has the same charge as the drug is delivered into the skin by electrostatic repulsion when electric current is applied. The rate of transport of a charged drug during iontophoresis is controlled by passive diffusion, migration due to electric current applied, and electroosmosis due to bulk fluid flow in the same direction as the flow of the counter ions. In addition to classical polymers, intelligent, stimuli-responsive polymers are also used as membrane material for controlling the release rate of drugs through the membrane. For example, hydrogel membranes manufactured from glucose-containing copolymers could respond to the dynamic changes in external glucose concentration, and this response can be used to control the release of insulin through the hydrogel membrane (Obaidat and Park 1997).

Controlled Release

Sacide Alsoy Altinkaya
Department of Chemical Engineering, Izmir
Institute of Technology, Urla, Izmir, Turkey

Controlled-release technologies are developed to deliver drugs, proteins, pesticides, fragrances, and other bioactive agents at a controlled rate for a desired time period to maintain a constant and effective level of an active ingredient. Controlled-release formulations provide greater

efficacy, convenience, and improved safety by maintaining optimal concentrations of the active ingredient. Many controlled-release technologies operate by diffusion of the active ingredient or water through a rate-controlling membrane and can be classified into four categories: (1) reservoir types, (2) matrix systems, (3) swelling-controlled systems, and (4) osmotic systems.

In reservoir (membrane) systems, the bioactive agent is either encapsulated by two semipermeable membranes or core containing the active ingredient is surrounded by a semipermeable membrane. Diffusivity and solubility of the active ingredient in the membrane are two key parameters that influence the rate of diffusion through the membrane. The size and shape of the active ingredient, the packing density, and the flexibility and crystallinity of polymer chains affect the diffusivity in the membrane. Solubility of the active ingredient in the polymer depends on its interaction with the membrane material.

In matrix (monolithic) systems, the bioactive agent is incorporated in a polymer either in dissolved or dispersed form. When the active ingredients are in liquid form, they are typically dissolved in polymer matrices, while solid ingredients are dispersed in the polymer. Release of the agent occurs by diffusion through the polymer matrix and solubility of the agent becomes a controlling factor.

Osmotic controlled-release systems are reservoir-type systems except that the release of the active agent depends on the diffusion of water into the membrane. In these systems, a semipermeable membrane that is much more permeable to water than to the active agent separates a core with high osmotic pressure from a solution with low osmotic pressure. Water penetration into the core generates a hydrostatic pressure within the core that forces the solution containing the active ingredient out through the membrane. Water permeability of the rate-controlling membrane determines the release rate of the active agent.

Swelling-controlled-release systems are similar to the design of matrix systems and usually consist of an active ingredient dispersed throughout a swellable polymer. In these systems, the active ingredient is not released until the polymer

matrix is swollen since the diffusivity of the active ingredient in the swollen matrix is several orders of magnitude higher than its diffusivity in the unswollen polymer.

Controlled-release systems that are not dependent on diffusion have also been developed. For example, in the case of bioerodible systems, the release rate is controlled by either polymer dissolution or a chemical reaction at the polymer surface; therefore, geometric shape of the release system is important. In pendant chain systems, the active agent is bound to a polymer backbone chain chemically and is released by hydrolytic or enzymatic cleavage. The agent can be attached directly or via a spacer group. The spacer group can be used to affect the release rate and hydrophilicity of the system. In a magnetically controlled-release system, the active agent is uniformly dispersed within a polymer matrix. The system releases the agent in a way typical of diffusion-controlled matrix systems upon exposure to aqueous media. On other hand, when the system is exposed to an oscillating external magnetic field, the release rate becomes much higher.

Various types of polymers have been used in the design of controlled-release systems. The choice of polymer can affect diffusion and partition coefficients in diffusion-controlled systems, the rate of erosion or hydrolysis in chemically-controlled systems, permeation rates of solvents in swelling-controlled systems, and mechanical forces in magnetically controlled systems.

Controlled Release by Membrane

Sacide Alsoy Altinkaya

Department of Chemical Engineering, Izmir
Institute of Technology, Urla, Izmir, Turkey

Many controlled-release systems commercially available now are based on membrane technology. These systems consist of a core containing the drug surrounded by a thin polymer membrane and transport of drug through membrane occurs by a solution-diffusion mechanism. Drug

molecules first dissolve in the membrane and then diffuse from interior part of the membrane to its surface. The diffusive flux through the membrane is described by Fick's first law of diffusion.

$$J = -D \frac{\partial C_m}{\partial x} \quad (1)$$

where D is the diffusivity of drug in the membrane, J is the flux of the drug, and C_m is the concentration of drug in the membrane. At the membrane surface, drug molecules choose to partition into either membrane or surrounding medium. The partition coefficient gives a measure of the preference of drug molecules between two phases. Defining the partition coefficient, K , as the ratio of the concentration in the membrane to the concentration in the solution, flux in Eq. 1 is rewritten as follows:

$$J = -DK \frac{\partial C}{\partial x} \quad (2)$$

where C is the concentration of drug in the surrounding medium. Under steady-state conditions, flux through the membrane is obtained by integrating Eq. 2.

$$J = DK \frac{\Delta C}{L} \quad (3)$$

Controlled-release systems based on membranes usually provide constant release rate as long as the concentration of drug within core is at saturation concentration. Deviations from constant release kinetics occur depending on the storage history of the release device. Time lag is observed when the system is used shortly after being manufactured while migration of the agent from the core into the membrane due to long-term storage causes initial burst effect. Equation 3 clearly shows that the release rate of drug is controlled by diffusivity and solubility of drug in the membrane as well as the thickness of the membrane. Diffusivity of drug in the membrane is influenced by the size and shape of the drug molecules, flexibility, packing density, or crystallinity of polymer chains. Flexibility of polymer chains depends on glass transition temperature and degree of crosslinking of the polymer. Diffusivities are higher in rubbery polymers than those in glassy polymers and

decrease as crosslinking density in the polymer increases. Diffusion takes place in the amorphous phase of the polymers; therefore, diffusivities are lower in more-crystalline polymers than in less-crystalline ones. Solubility of drugs in the membrane depends on the interaction between the polymer and drug. Simply, solubility of drug is higher in polymers containing similar functional groups with those of drug, in addition, solubility decreases with an increase in crystallinity of the polymer. Design of membrane-based controlled-release system for a particular drug requires to choose an appropriate polymer as a membrane material and appropriate thickness to adjust the release rate at a desired level.

Diffusion-controlled release systems are commonly used in commercial products and the most successful example is in transdermal applications. These devices contain the drug either in a reservoir surrounded by a membrane or dispersed in a polymeric matrix and deliver drugs directly through the skin and into the bloodstream. The flux of the drug through the skin is enhanced by using penetration enhancers or electric current. Osmotic controlled-release systems also depend on diffusion of water across a semipermeable membrane. These systems for oral delivery of drugs are prepared by compressing an osmotically active agent into a tablet, coating the tablet with a semipermeable membrane, and drilling a small hole through the coating. As water permeates through the membrane into the tablet, a solution of the agent is pumped out of the hole. Such a device provides a constant rate of release as drug traverses the gastrointestinal tract.

Controlled Release Dose

Sacide Alsoy Altinkaya

Department of Chemical Engineering, Izmir
Institute of Technology, Urla, Izmir, Turkey

Controlled release dosage forms are designed to deliver optimum dose of drug at the right time and right place. For an efficient and nontoxic therapy, the drug concentration in plasma should lie within the therapeutic range which is bounded below by the minimum effective concentration (MEC) and above by the minimum toxic concentration (MTC) as shown in Fig. 1. Conventional doses lead to a rapid rise and fall in the drug concentration; therefore, several doses at regular intervals are required to maintain effective levels. After an initial rise, controlled release dosage forms maintain a constant concentration in plasma between MEC and MTC. As a result, several benefits are achieved with these systems including a prolonged therapeutic effect, increasing short half-life of drugs, reduction in dosing frequency and side effects, and improved patient compliance. As shown in Fig. 1, zero-order release allows the best control of plasma concentration and controlled release dosage forms following zero-order release kinetics are usually achieved by using a rate-limiting membrane that is permeable to both drug and water. Osmotic pumping and solution-diffusion mechanism control drug release from membrane systems. In an elementary

Controlled Release Dose,

Fig. 1 The change in drug concentration in blood during drug delivery

osmotic pump, a table or capsule containing drug in the core is surrounded by a membrane that is permeable to water but not drug. After swallowing, water permeated into the core through the membrane dissolves drug, and a constant osmotic pressure gradient established pumps the drug through a hole drilled into the membrane. Zero-order release kinetics are observed so long as a constant osmotic pressure gradient between core and surrounding medium is maintained. When drug concentration falls below its solubility, then rate of drug release starts to decay. To improve the efficiency of osmotic systems, excipients such as water-soluble polymers are added into core, or drug formulation is placed between the water-soluble polymer and the exit orifice. A majority of the coated dosage forms are controlled by solution-diffusion mechanism where the driving force for the diffusional drug release is the drug concentration gradient across the rate-controlling membrane. The drug release rate can be manipulated by varying the membrane thickness and membrane permeability. Permeability can be modified by incorporating soluble additives or pore-forming agents in the membrane material which allows the drug release not only by diffusion but also by osmotic pumping.

To develop a controlled release dosage form, relevant pharmacokinetic parameters for the absorption, distribution, and elimination of a drug as well as its in vivo release profile from the dosage form should be considered. The dosage form should deliver the drug within 24 h which corresponds to the total gastrointestinal tract (GI) transit time in humans. To protect drug from hydrolysis in acidic environment of the stomach, dosage forms are prepared with membranes made from pH-sensitive polymers that are insoluble in acid but dissolve in the neutral or slightly alkaline environment of the gut. Drug is released rapidly if the molecular weight of the polymer is low. If a high molecular weight, water-soluble polymer is used for coating, initially it swells into a gel through which drug diffuses. Following ingestion, the rate of swelling and diffusion through the membrane affect the time for passage of the dosage form through the stomach to the small intestine.

Controlled Release Kinetics

Sacide Alsoy Altinkaya

Department of Chemical Engineering, Izmir
Institute of Technology, Urla, Izmir, Turkey

The release of an active agent from controlled release systems can be categorized into three types: (1) zero-order release kinetics, (2) $t^{-1/2}$ kinetics, and (3) first-order kinetics. In reservoir (membrane) systems, the active ingredient is usually encapsulated between two semipermeable membrane, and the release rate is controlled by diffusion through the membrane. Reservoir systems generally provide a zero-order release where the release rate remains constant until all of the active ingredient has been delivered. The release kinetics from reservoir systems in the form of a flat sheet is described by the following equation:

$$\frac{dM_t}{dt} = ADK \frac{\Delta C}{L} \quad (1)$$

where

M_t = mass of the active agent released up to time t

A = surface area

L = thickness of the rate-controlling membrane

D = diffusivity of the active agent through the membrane

K = partition coefficient of the active agent through the membrane

When the concentration of the active ingredient within the reservoir is less than its saturation value, then the concentration difference through the membrane decreases with time, and first-order release kinetics is observed which can be expressed as follows:

$$\frac{dM_t}{dt} = \frac{C_s ADK}{L} \exp\left(-\frac{ADKt}{VL}\right) \quad (2)$$

where C_s is the saturation concentration of the agent and V is the volume of the reservoir and t is time.

In matrix systems, active ingredients are dissolved or dispersed through a polymer and release rates from these systems decrease with time. Release kinetics from matrix systems containing dissolved active agents is described by a combination of first-order and $t^{-1/2}$ kinetics as follows (Baker and Lonsdale 1974):

$$\begin{aligned} \frac{M_t}{M_\infty} < 0.6 \quad \frac{dM_t}{dt} &= 2M_\infty \left(\frac{D}{\pi L^2 t} \right)^{1/2} \\ \frac{M_t}{M_\infty} > 0.6 \quad \frac{dM_t}{dt} &= \frac{8DM_\infty}{L^2} \exp \left(-\frac{\pi^2 D t}{L^2} \right) \quad (3) \end{aligned}$$

where M_∞ is the total amount of active ingredient initially loaded into the matrix. When active agent is dispersed throughout the polymer, $t^{-1/2}$ kinetics is observed and the release rate is predicted by Eq. 4 (Baker and Lonsdale 1974):

$$\frac{dM_t}{dt} = \frac{A}{2} \left(\frac{DC_{ms}(2C_\infty - C_{ms})}{t} \right)^{1/2} \quad (4)$$

where C_{ms} is the saturation concentration of the active ingredient in the polymer and C_∞ is the concentration of active ingredient initially loaded into polymer matrix.

Osmotic-controlled release which is usually reservoir-type systems follow zero-order release kinetics as long as the osmotic pressure gradient through the membrane is constant. The release rate of the active agent from these types of systems is defined with the following equation (Theeuwes et al. 1983):

$$\frac{dM_t}{dt} = \frac{AP_w \Delta \pi C_{sa}}{L} \quad (5)$$

where P_w is the permeability of water through the membrane, $\Delta \pi$ is the osmotic pressure difference, and C_{sa} is the solubility of the active agent in the membrane.

In swelling-controlled release systems, the release rate depends on the degree of swelling of the matrix which is influenced both by the diffusion of solvent into the polymer and relaxation of the polymer chains. When diffusion is the rate-controlling step, $t^{-1/2}$ kinetics is observed and the

release controlled by relaxation follows zero-order release kinetics (Alfrey et al. 1966).

Convective Transport

Boguslaw Kruczek

Department of Chemical and Biological Engineering, University of Ottawa, Ottawa, ON, Canada

Introduction

Convective transport (convective flow, bulk flow, convection) may refer to either heat or mass transfer. Convective transport takes place both by diffusion, i.e., the random Brownian motion of individual particles in the fluid, and by advection, in which matter or heat is transported by the larger-scale motion of currents in the fluid. Convective transport is used to refer to the sum of advection and diffusion (Bergman et al. 2011). Convective mass transfer cannot take place in solids, because neither bulk current flows nor significant diffusion can take place in solids, but it can take place in porous solids. Diffusion of heat can take place in solids and is referred to as heat conduction. In the context of membranes, convective flow refers to the transport of fluid (pure solvent or solution) across a porous membrane, which is driven by the applied pressure. Convective transport is the main mode of transport in microfiltration and ultrafiltration processes; it may also contribute to the transport in diffusion dialysis if the pressure is applied. Convective

transport may occur in gas separation membranes if pinholes (defects) are present in the membrane structure, which is undesirable because it diminishes the selectivity of the membrane.

Microfiltration and Ultrafiltration

Ultrafiltration and microfiltration membranes are both considered as porous membranes in which rejection is mainly determined by the size and shape of solute relative to the pore size of the membrane and where the transport of solvent is directly proportional to the applied pressure. For laminar convective flow through a porous membrane, both the Hagen-Poiseuille and the Carman-Kozeny equations can be applied (Mulder 1996). If the membrane consists of straight capillaries, the Hagen-Poiseuille relationship is applicable in which the mass velocity of fluid (N) through the membrane is given by

$$N = \frac{\varepsilon \rho D^2}{32 \mu L \tau} \Delta p \quad (1)$$

where ρ and μ are the density and viscosity of the fluid and ε , D , L , and τ are the porosity, pore diameter, thickness, and tortuosity of the membrane, respectively. For a cylindrical perpendicular pore, $\tau = 1$. If the pore is not straight, the product $L\tau$ represents the actual length of the pore. When membrane has a nodular structure, i.e., it is an assembly of spherical particles, the pores are not cylindrical and straight; Carman-Kozeny equation is then employed (Seader et al. 2011):

$$N = \frac{\varepsilon^3 \rho}{2(1 - \varepsilon)^2 a_v^2 \mu \tau L} \Delta p \quad (2)$$

Equation 2 is obtained by replacing the pore diameter in Eq. 1 by the hydraulic diameter (D_H):

$$D_H = \frac{4A_p}{P} = \frac{4\varepsilon}{a_v(1 - \varepsilon)} \quad (3)$$

where A_p is the cross-sectional area of the pore and P is the wetted perimeter of the pore, which

are then expressed in terms of the specific surface area, a_v , and the porosity of the membrane, ε , (Seader et al. 2011). Equation 2 is obtained by substituting Eq. 3 into Eq. 1.

Equation 2 is sometimes presented in an alternative form (Mulder 1996):

$$N = \frac{\varepsilon^3 \rho}{K(1 - \varepsilon)^2 a_v^2 \mu L} \Delta p \quad (4)$$

where K is the Carman-Kozeny constant, which depends on the shape of the pores and the tortuosity. The commonly used value $K = 5$ implies the membrane tortuosity $\tau = 2.5$.

Gas Permeation

Gas separation requires membranes to be nonporous (e.g., polymeric membranes) or ultramicroporous, i.e., with pores smaller than 0.7 nm diameter (e.g., zeolite and carbon membranes). The pores greater than 2 nm are considered to be defects, because they offer limited (Knudsen flow) or no selectivity (convective flow) for gas separation. The actual mechanism of gas transport through the defects depends on the ratio of the pore diameter (D) and the mean free path of gas molecules (λ):

$$\lambda = \frac{3\mu}{2p} \left(\frac{\pi RT}{2M} \right)^{1/2} \quad (5)$$

where T is the absolute temperature, R is the universal gas constant, P is the pressure, and M is the molecular weight of the gas. If $D/\lambda \gg 1$, i.e., the collisions between gas molecules are more frequent than the collisions with the pore walls, and there is a pressure gradient across the membrane, the convective transport dominates. Since gases are compressible, Eqs. 1, 2, and 4 are applicable in a differential form. Using the ideal gas law, gas density can be expressed by

$$\rho = \frac{pM}{RT} \quad (6)$$

Assuming defects to be straight cylindrical pores, Eq. 1 becomes:

$$N = \frac{\varepsilon D^2 M p}{32 \mu R T} \frac{dp}{dx} \quad (7)$$

At steady state the flux is constant; integrating Eq. 7 from the feed side ($x = 0, p = p_o$) to the permeate side ($x = L, p = p_L$) leads, after rearrangements, (Kesting and Fritzsche 1993) to:

$$N = \frac{\varepsilon D^2 M}{32 \mu R T} \frac{(p_o + p_L)}{2} \frac{(p_o - p_L)}{L} \quad (8)$$

where p_o and p_L are the feed and permeate pressures, respectively.

Dialysis

Diffusion dialysis is a rate-governed membrane process in which solutes are driven across a porous membrane by means of a concentration gradient. When a pressure gradient is applied, in addition to diffusive transport, the solutes may also be transported by the convective flow. The pressure gradient may be applied in order to concentrate the feed, or may be obligatory as a consequence of the geometry of the dialysis device and the desired feed flow rate. On the other hand, in the case of highly concentrated feed, the convective flow may occur from diluted dialysate (permeate) to the feed in response to an osmotic pressure gradient. At steady state, the solute flux (N_s) at a point on the membrane consists of the sum of a diffusive and convective component (Kessler and Klein 1992):

$$N_s = P_m \Delta c_s + N_v (1 - \sigma) \bar{c}_s \quad (9)$$

where P_m is the diffusive permeability of solute, Δc_s is the concentration gradient of solute across the membrane, N_v is the volumetric flux (superficial velocity) of solvent, σ is the reflection coefficient, and $\bar{c}_s$ is the average solute concentration within the membrane. The second term of Eq. 9, $N_v (1 - \sigma) \bar{c}_s$, represents the convective component of the total solute transfer.

Conventional Pretreatment of Water

A. Moura Bernardes
Universidade Federal do Rio Grande do Sul
(PPGE3M-UFRGS), RS, Porto Alegre, Brazil

Conventional pretreatment of water is the process and operation applied to the treatment of water or wastewater prior to the feeding of the membrane separation process (MSP).

In membrane processes, the nature of the feed stream is very important, since the presence of colloidal material leads to clogging and adsorption phenomena that alter the mechanisms of operation (Minhalma 2001). Many feed solutions used for the production of potable or industrial process water contain suspended and colloidal matter or soluble salts close to their saturation level. These components cause severe membrane fouling and poisoning. A pretreatment of the feed solution, which guarantees the removal of these materials, is therefore mandatory for a trouble-free operation of membrane separation processes (Strathmann 2004).

Water pretreatment processes are chosen mainly based on the initial type (seawater, brackish water, surface water, wastewater) and quality of the water with respect to the type of foulants (suspended solids, bacteria, organics). Typical methods of pretreatment are the addition of an oxidant (to remove bacteria, algae), coagulation/flocculation (to remove suspended solids), pH adjustment (to prevent scaling), adsorption on activated carbon, and all types of filters such as multilayers and cartridge filters (Nobles and Stern 1995). The integration of flotation processes to coagulation/flocculation steps is also envisaged (Geraldes et al. 2008). Figure 1 presents a summary of the pretreatment processes applied to MSP.

Besides the feed quality, a classification must also be made among different membrane separation processes. Each desalting technology has different requirements for the quality and condition of water entering the process. For membrane processes, the major concerns are membrane fouling and scaling, suspended solid plugging, biological fouling or attack, membrane degradation by oxidation, or other means (Watson et al. 2003).

To lower pressure processes as microfiltration (MF) and ultrafiltration (UF), pretreatment may include chemical coagulation, chlorination, screening, and flow equalization. If the raw water turbidity and/or NOM (natural organic matter) concentration is high, pretreatment will include coagulation, flocculation, and sedimentation. The effect of coagulation is site specific due to interactions between the coagulants, raw water components, and the membrane. In some cases, especially for UF processes, low coagulant doses may cause greater fouling than no coagulation, but higher doses for enhanced coagulation frequently reduce fouling. When iron and manganese are prevalent in the raw water, oxidation may be performed to form a precipitate that can be removed by coagulation. Nevertheless, the use of oxidants requires careful selection of the membrane material, as well as precautions to remove residual oxidant before the membrane treatment step (Davis 2011).

In nanofiltration (NF), reverse osmosis (RO), and electrodialysis (ED), the selection of the

pretreatment will also depend on the feed water composition and its variability, but will always comprise a step of solids and turbidity removal and other step of organic compounds removal. Most often, it uses physicochemical processes to remove solids and activated carbon filters to remove organics (Bernardes et al. 2014).

By NF and RO processes, it is important to prevent scaling by silica and sparingly soluble salts such as calcium carbonate and calcium sulfate. Besides silica, calcium carbonate, and calcium sulfate, the other salts that most commonly form scale are barium sulfate, strontium sulfate, and calcium fluoride (Rautenbach and Melin 2004; Baker 2012). Scale control consists of pH adjustment and a softening process. After softening, the effluent is usually further clarified, for example, by sand filtration (Scott 1995). Filtration is used to remove particulate matter that will clog the feed channels or accumulate on the membrane surface. The minimum filtration requirement regardless of the water source is a cartridge filter rated in the 1–25 μm range with a typical rating of 5 μm (Davis 2011). The RO units are fitted with a 0.45 μm cartridge filter, and a sand filter, sometimes supplemented by addition of a flocculating chemical such as alum or a cationic polymer, may be required (Baker 2012). Disinfection by chlorination, ozonation, or UV irradiation may also be required to prevent biofouling (Davis 2011). If chlorine is used, residual chlorine must be removed when polyamide and interfacial composite membranes are used, since these are chlorine sensitive. The development of low-cost MF/UF membrane processes that remove particulate and bacteria has encouraged the use of these membranes as a pretreatment step for RO (Baker 2012).

Although for electrodialysis the water pretreatment is also an important task, comparing to RO, electrodialysis (ED) demands less pretreatment operations. ED only removes ions. Therefore, any bacteria, colloidal material, or silica present in the feed water stream will remain in the product stream. This can be a disadvantage, especially for the production of drinking water, because as only ions are removed, uncharged components such as microorganisms or organic

Conventional Pretreatment of Water, Fig. 1 Summary of the pretreatment processes applied to MSP

contaminants are not eliminated (Bernardes et al. 2014). On the other hand, it brings benefits when, for example, silica is present. Silica occurs in varying concentrations in all natural waters. RO membranes reject silica, but silica is largely unaffected by passage through an ED system. Consequently, silica precipitation is not of concern in

ED plant (Watson et al. 2003). By ED, there is also a possibility of fouling minimization by reversing the polarity of the system several times per hour with electrodialysis reversal (EDR). By reversing the polarity (and the solution's flow direction), ions move in the opposite direction through the membranes, minimizing buildup. This generally

minimizes membrane fouling, decreasing pretreatment requirements in comparison to RO (Bernardes et al. 2014). Since microorganisms are not removed from a feed stream by electrodialysis, most commonly a chlorination of the product water is required. When the concentrate stream has been acidified, the product water pH value must be readjusted. Other measurements may be necessary depending on the feed water composition and required product water quality (Strathmann 2004). Feed waters containing significant quantities of calcium carbonates and bicarbonates are likely to cause precipitation in the concentrate stream at the anion-exchange membrane surface due to pH changes resulting from water splitting which is obtained when the limiting current density is exceeded locally (Strathmann 2004). Organic fouling of ion exchange membranes is one of the major problems in electrodialysis. It is caused by the precipitation of colloids on the membranes, and since most of the colloids present in natural water are negatively charged, it is usually the anion-exchange membranes which are affected. Certain detergents are also the cause of this type of poisoning, which is very difficult to deal with and can best be avoided by a proper pretreatment of the feed solution (Strathmann 2004; Baker 2012). The usual method for removing colloidal material is the pretreatment by coagulation-flocculation and filtration. In this step, some chemicals are used to assist in removal of solids and turbidity as coagulants, flocculants, acids, or bases to adjust pH and oxidizing agent for organic matter degradation. When using membrane process for solid removal, a preliminary step of coagulation may be needed, to increase the efficiency of removal of colloids and/or oxidation. Organic compounds that were not degraded in biological treatment can be removed in activated carbon filters. In this step, it is important to control the generation of fine carbon and, if necessary, adopt operational changes in order to prevent clogging of the cartridge filter and passage into the membrane modules of the electrodialysis. Cartridge filters are also used upstream of electrodialysis as the ultimate protection against suspended solids (Bernardes et al. 2014). Hydrogen sulfide, H_2S , is a frequent

constituent of groundwater along the coast or at other locations where wetlands have existed. Hydrogen sulfide is a by-product of the life cycle of sulfate-reducing bacteria (SRB) that are common in many groundwater systems. Like all gases, H_2S is passed by RO membranes and appears in both the permeate and the concentrate, not being of concern in RO plants. On the other hand, H_2S must be removed from the feed water to ED/EDR plants to prevent oxidation of H_2S in the stack and the resultant membrane fouling by colloidal sulfur. Oxidation occurs by reaction with both the chlorine and oxygen produced by electrolysis in the process. The most common treatment is air stripping, followed by (usually) chlorination to complete the oxidation of the remaining sulfide, and granular filtration (Watson et al. 2003).

Copolyimide Precursors

Tauqir A. Sherazi

Department of Chemistry, COMSATS Institute of Information Technology, Abbottabad, Pakistan

Polyimide Precursors

Polyimides are a class of thermally stable polymers that are often based on stiff aromatic backbones derived from aromatic dianhydrides and aromatic diamines. Polyimides due to their unusual properties are finding a wide range of applications and thus used as precursor (a precursor is a compound that participates in the chemical reaction that produces another compound) to develop materials for various applications. The chemistry of polyimides is in itself a vast area with a large variety of monomers available and several methodologies available for synthesis.

The general formula and chemical structure of polyimide is shown in Fig. 1.

Few of the specialty properties of polyimides include:

High thermal and thermo-oxidative stability up to 400 °C (750 °F)

Excellent mechanical properties, both at room temperature and elevated temperatures

Film- and fiber-forming ability

Excellent adhesive properties, both at room temperature and elevated temperature

Nonflammability – will not support combustion

Applications of Polyimide Precursors

Owing to its excellent chemical and thermal stability, polyimides have wide range of applications

such as in electronics, aircraft, automobile, medical, machining, gas purification, aerospace, and military applications.

For application in electronic and microelectronics industry, fluorine may be introduced to polyimides which reduced the dielectric constant along with retaining the other characteristics mentioned above (Hermciuc et al. 2000). Formation of nanofoam polyimides is a novel approach for reducing the dielectric constant. Basically in nanofoam formation, polyimide polymer replaces with air which reduces the dielectric constant (Hedrick and Charlier 1994). The membrane developed by polyimide containing functional or pendant groups in the backbone of the aromatic dianhydride and/or diamine exhibits good as well as selective gas permeability.

Hyperbranched polyimide (HBPI) precursors were also studied to develop high-performance carbon molecular sieve membranes for improved gas separation applications. It was found that the unique hyperbranched network structure found in HBPI possesses great potential to produce carbon molecular sieve membranes with superior performance (Sim et al. 2013). It is also reported that the membrane produced from the pyrolysis of a hollow-fiber polyimide precursor under suitable conditions has good separation properties when applied to mixed gas pairs, such as O₂/N₂, CO₂/CH₄, and H₂/CH₄ (Jones and Koros 1994). Polyimide-based membranes have been extensively studied for removal of CO₂ particularly from natural gas and found few of them quite efficient (Xiao et al. 2009). Soluble and optically transparent fluorine-containing photoreactive polyimide precursors were developed. These precursors offer high-resolution patterns with aspect ratio of more than 2.0. In these polyimide precursors, the polymers which have a benzophenone segment in the polymer backbone are self-sensitized and show interesting photochemical reactions (Omote et al. 1989).

Polyimide processability is one of the issues associated which cause hurdle to manufacture polyimide parts, such as composites, at costs competitive to other metal parts. Improvement in polyimide processability is essential which could

Copolyimide Precursors,
Fig. 1 Chemical structure
of polyimide

be achieved by reduction in its melt viscosity. Low-molecular-weight end-capped oligomers are potential candidates for the development of polyimide oligomers for improved processability (Smith and Connell 2000; Simone and Scola 2000).

Copper Removal and Recovery by Supported Liquid Membranes

Carlos Moreno

Department of Analytical Chemistry, Faculty of Marine and Environmental Sciences, University of Cádiz, Puerto Real, Spain

Copper is an element that occurs naturally as a metal or as part of sulfide minerals, such as chalcopyrite or bornite, as well as oxides and carbonate ores.

It has been used by human being from the ancient age and today is still extensively applied in many areas that cover a wide variety of different disciplines. It is used mostly as copper metal or copper alloys (electrical devices and wires, coins, pipes, automotive industry, etc.) and also as copper salts (agriculture, water purification, etc.).

This extensive use produces a huge amount of residual wastes containing copper, which may lead to environmental pollution and then justifying a previous treatment to remove and recover copper ions.

Although in general the stability of supported liquid membranes may represent an important difficulty for large-scale operations, recovery of copper was successfully conducted at pilot scale on a hollow-fiber membrane contactor with a surface area of 130 m² (Yan and Kocherginsky 2006).

Copper Removal and Recovery by Supported Liquid Membranes,

Fig. 1 Chemical structure of a ketoxime (1) and 5-nonylsalicylaldoxime (2)

On the other hand, copper is an essential element that takes part in several biogeochemical processes, most of them at very low concentrations. This fact has led to the growing development of hollow-fiber supported liquid membrane systems for analytical sample treatment to the determination of copper traces in environmental samples.

Copper separation though supported liquid membranes may be performed by using a variety of carriers in the organic membrane, mainly organophosphorus acidic compounds (see *Cobalt removal and recovery by supported liquid membranes*) or commercial mixtures of oximes, mostly ketoximes (1) and salicylaldoximes, such as 5-nonylsalicylaldoxime (2), which form complexes with copper ions (Fig. 1).

Corrosion

C. V. Vedavyasan
Department of Technology, Annamalai
University, Chidambaram, Tamil Nadu, India

Introduction

Corrosion is the gradual process of wearing, weaning away, and thinning down the metal surface by the fluid with which it is in contact. Millions of dollars are lost every year due to corrosion

of iron and steel. Other metals do corrode. The oxide formed by oxidation does not firmly adhere to the surface of the metal and flakes off easily causing “pitting”. Continued pitting causes structural weakness and disintegration of the metal. Metals such as aluminum form a tough oxide coating onto the surface to prevent corrosion.

In some circles, corrosion has been described as the tendency of a metal to revert to its natural stable state as an ore. The process may involve a second step in which an oxide, hydroxide, or carbonate of the metal may form and deposit at the corrosion site. Thus, corrosion takes place when a metal dissolves in or is disintegrated by water.

Different metals have different tendencies to corrode or not to corrode in the same water. A certain type of water may corrode one metal and not another, but the reverse may be true for another type of water. An excellent method for corrosion control in water heaters is cathodic protection involving the use of a sacrificial anode, usually composed of magnesium or aluminum. Chemical control of corrosion attempts to retard electrode reactions.

The Mechanism and Chemistry of Corrosion Reactions

Corrosion reactions are electrochemical in nature. They involve the transfer of charged ions across the surface between a metal and the electrolyte in which the metal is immersed. There are two types of electrode reaction occurring at the metal surface: anodic and cathodic.

Corrosion occurs in the presence of moisture. When iron is exposed to moist air, it reacts with oxygen to form rust. The amount of water <http://www.corrosion.com>, precisely the number of molecules of water, present determines the color of rust varying from black to yellow to orange brown. The formation of rust is a very complex process which begins with the oxidation of iron to ferrous (+2) ions.

In an anodic reaction, electrons appear on the right-hand side. An example is shown below:

Both water and oxygen are required for the sequence of reactions. Iron (+2) ions are further oxidized to form ferric ions (iron⁺³) ions:

The electrons provided from both oxidation steps are used to reduce oxygen as shown. Cathodic reactions involve electrochemical reduction wherein electrons appear on the left side:

The ferric ions then combine with oxygen to form ferric oxide [iron (III) oxide] which is then hydrated with varying amounts of water. The reduction of oxygen at an electrode will cause a rise in pH due to production of hydroxide ion. The equation for rust formation is

The formation of rust can occur at some distance from the actual pitting or erosion of iron. The electrons produced via the initial oxidation of iron can be conducted through the metal, and the iron ions can diffuse through the water layer to another point on the metal surface where oxygen is available. This process results in an electrochemical cell in which iron serves as anode, oxygen gas as the cathode, and iron solution as “salt bridge”. The

involvement of water accounts for the fact that rusting occurs much more rapidly in moist environment as compared to dry one. The mechanism of corrosion is shown in Fig. 1 below.

Influence of Salt on Corrosion

The presence of salt enhances the rate of corrosion. As the dissolved salt increases, the conductivity of the aqueous solution at the metal surface enhances the rate of electrochemical corrosion. Hence iron and steel corrode more rapidly when exposed to salt or moist salty air near the ocean.

Factors Associated Mainly with the Metal

- Effective electrode potential of a metal in a solution
- Overvoltage of hydrogen on the metal
- Chemical and physical homogeneity of the metal surface
- Inherent ability to form an insoluble protective film

Factors Varying with the Environment

- pH of the solution
- Influence of oxygen in solution adjacent to the metal

Forms of Corrosion

Galvanic Corrosion

This is an electrochemical action of two dissimilar metals in the presence of an electrolyte and an electron conductive path. It occurs when

Corrosion, Fig. 1 The mechanism of corrosion

Corrosion, Fig. 2 Galvanic corrosion

dissimilar metals are in contact. It is recognizable by the presence of a buildup of corrosion at the joint between the dissimilar metals. When aluminum or magnesium alloys are in contact with carbon or stainless steel, galvanic corrosion occurs and accelerates the corrosion of aluminum or magnesium (Fig. 2).

Galvanized steel
Zinc
Magnesium alloys
Magnesium

Anodic (Most Active) The natural differences in metal potentials produce galvanic differences, such as the galvanic series in sea water. If electrical contact is made between any two of these materials in the presence of an electrolyte, current must flow between them. The farther apart the metals are in the galvanic series, the greater the galvanic corrosion effect or the rate. Metals or alloys at the upper end are noble while those at the lower end are active. The more active metal is the anode or the one that will corrode. The anode must be chosen from the above material list which is lower on the list than the material to be protected.

Control of galvanic corrosion is achieved by using metals closer to each other in the galvanic series or by electrically isolating metals from each other. Cathodic protection can be used to control galvanic corrosion effects.

The following practices are recommended to keep galvanic corrosion to a minimum.

- Avoid the use of widely dissimilar metals in direct contact.

Corrosion,**Fig. 3** Isolation flanges to prevent galvanic

- When dissimilar metals must come into contact, they should be separated by using nonconductive barrier materials, a paint coating, or by plating.
- The anode should be as large as feasible in relation to cathode.
- Coat both the anode and the cathode with the same material.
- Install fasteners that have been dipped in epoxy mastic coatings.
- Seal threaded inserts with epoxy mastic coatings prior to insertion into castings.
- Avoid the use of lock or toothed washers over plated or anodized surfaces.

The scuba tank above suffered galvanic corrosion when the brass valve and the steel tank were wetted by condensation. Electrical isolation flanges (Fig. 3) like those shown on the right are used to prevent galvanic corrosion. Insulating polymeric gaskets are inserted between the flanges, and insulating sleeves and washers isolate the bolted connections.

Pitting Corrosion

The most common effect of corrosion on aluminum and magnesium alloys is pitting. First is noticeable as a white or gray powder, similar to dust, which blotches the surface. When the deposit is cleaned away, tiny pits or holes can be seen in the surface. Passive metals such as

stainless steel resist corrosive media and can perform well over long periods of time. However, if corrosion does occur, it forms at random pits. Pitting may be a serious type of corrosion because it tends to penetrate rapidly into the metal section. It is most likely to occur in the presence of chloride ions, combined with such depolarizers as oxygen or oxidizing salts. Methods that can be used to control pitting include maintaining clean surfaces, application of a protective coating, and use of inhibitors or cathodic protection for immersion service.

Sometimes pitting corrosion can be quite small on the surface and very large below the surface. The figure below left shows this effect common on stainless steel and other film-protected metals. Pitting shown on the right (white arrow) led to the stress corrosion fracture shown by the black arrows (Fig. 4).

Pitting corrosion can lead to unexpected catastrophic system failure. The split tubing below left was caused by pitting corrosion of stainless steel. A typical pit on this tubing is shown below right (Fig. 5).

Stress Corrosion Cracking

Stress corrosion cracking (SCC) is caused by the simultaneous effects of tensile stress and corrosion. Stress may be internally or externally applied. Internal stresses are produced by nonuniform deformation during cold working,

Corrosion, Fig. 4 Same images for pitting corrosion

Corrosion, Fig. 5 Pitting corrosion for stainless steel tube

by an unequal cooling from high temperatures, and by internal structural rearrangement involving volume changes. Stresses induced when a piece is deformed, those induced by press and shrink fits, and those in rivets and bolts are internal stresses. Concealed stress is more important than design stress, especially because stress corrosion is difficult to recognize before it has overcome the design factor. Few guidelines in avoiding the problem are:

- Use metal alloys at no greater than 75 % of their yield strength and use exotic materials only where they are actually required.
- Avoid assemblies where high-tensile loads are concentrated in a small area.
- Remove stress risers from counter bores, grooves, etc.

Crevice Corrosion

Crevice or contact corrosion is produced at the region of contact of metals with metals or metals with nonmetals. It may occur at washers, under barnacles, at sand grains, under applied protective films, and at pockets formed by threaded joints. Whether or not stainless steels are free of pit nuclei, they are always susceptible to this kind of corrosion because a nucleus is not necessary. Crevice corrosion may begin through the action of an oxygen concentration cell and continue to form pitting. Cleanliness, the proper use of sealants, and protective coatings are effective means of controlling this problem.

Intergranular Corrosion

This is an attack on the grain boundaries of a metal or alloy. A highly magnified cross section of any

commercial alloy will show its granular structure. This structure consists of quantities of individual grains, and each of these tiny grains has a clearly defined boundary that chemically differs from the metal within the grain center. One example of this type of corrosion is in unstabilized 300-series stainless steels sensitized by welding or brazing and subsequently subjected to a severe corrosion environment. Another example of intergranular or grain boundary corrosion is that which occurs when aluminum alloys are in contact with steel in the presence of an electrolyte. The aluminum alloy grain boundaries are anodic to both the aluminum alloy grain and the steel. In the later case, intergranular corrosion of the aluminum alloy occurs. Some austenitic steels are unstable when heated in the temperature range 470–915 °C.

Decreased corrosion resistance in austenitic stainless steels is due to depletion of chromium in the area near the grain boundaries, caused by the precipitation of chromium carbide. This condition can be eliminated by the use of stabilized stainless steel, such as columbium-, tantalum-, or titanium-stabilized stainless steels (types 321/347), or by the use of low-carbon stainless steels. Molybdenum additions as in type 316 stainless steels decrease the sensitivity to and the severity of the intergranular attack.

Intergranular corrosion can be prevented by:

- Select an alloy type that is resistant to intergranular corrosion.
- Avoid heat treatments or service exposure that makes a material susceptible. Normally this occurs with austenitic stainless steels when they are held for some time in the sensitizing temperature range of 470–915 °C (800–1600 °F).
- Apply a protective coating.

Corrosion Removal

Abrasive blasting is the preferred method of removing corrosion; other mechanical methods used are grinding, chipping, sanding, or wire brushing.

Remove corrosion by *mechanical method* such as wire brushing or abrasive blasting as

appropriate. Failure to adequately clean all residues will permit corrosion to continue. Light corrosion may be removed from thin members – ducts and tubing – with a nonwoven, nonmetallic abrasive mat in accordance with MIL-A-9962 or number 400 aluminum oxide or silicon carbide grit abrasive paper or cloth. Do not use steel wool.

Chemical Method

Chemical corrosion-removal methods can be used when no danger exists that the chemical used will become entrapped in recesses and when there is no danger that adjacent material will be attacked. The chemical method should be used on complex shapes and machined surfaces. Chemical rust removers are of two types: acid or alkaline. The acid type is used in removing rust and black oxide by immersion or brush application. This is a phosphoric acid-type remover and must not be used on high-strength steel heat treated above 1.24 gigapascals (GPa) tensile strength due to possible stress corrosion or hydrogen embrittlement problems. The alkaline type (sodium hydroxide base) is suitable for use by immersion only. Use on machined surfaces where a dimensional change would be objectionable.

Scale conditioners are used as necessary to facilitate oxide scale removal by acid cleaning. The use of scale conditioners shall not cause pitting, intergranular attack, or reduction of mechanical properties below the minimum values as specified in the applicable material specification for the alloy, gage, and heat-treat condition.

When acid cleaning is used to remove heat-treat scale, flux, corrosive media, stains, and other contaminants, it shall be within the limits specified. Acid cleaning shall not result in intergranular attack that would be detrimental to the fabrication or use of the material or part. Acid cleaning shall not result in pitting or smutting, which will not be readily removed by subsequent processing. Cleaning shall be accomplished in the following bath:

1. Nitric acid (HNO_3) (42 Baume)
225–375 kg/m³

2. Hydrofluoric acid (HF) or NH_4HF_2 9–52 kg/m³
3. Temperature: room 60 °C (140 °F)
4. Metal content, HF ratio = 1: 1.8 (replenish bath when the metal concentration >1 part of metal to 1.8 parts of HF)

Stainless Steel Alloys

Stainless steels owe their inherent corrosion resistance to a condition known as passivity – as a result of the presence of their oxide films called “passive films.” Under favorable conditions, such films are protective; however, unfavorable conditions deficient in oxygen will destroy the films and leave the surface in an “active” state with corrosion resistance comparable to carbon steel. The presence of hygroscopic salt deposits, dirt, dust, and other foreign matter all serve to destroy passivity. Underground exposure of bare stainless steel will result in unacceptable quality. Where localized corrosion occurs, rapid penetration (pitting) at the point of initiation can occur as an electrolytic cell is formed between the large cathodic (passive) area and the small anodic area under attack. This attack is particularly severe in the presence of halide salts. Localized attack will also occur in crevices, such as under sleeves on tube fittings.

Superior resistance to pitting is attainable with type 904 L unified numbering system (UNS) N08904 stainless steel over other commonly used steels. However, this is only a matter of degree and localized attack can still occur. Maintaining clean surfaces will greatly reduce the opportunity for corrosion, regardless of the alloy employed.

Typical Problem Areas

- **Sharp edges.** Sharp edges of metal structures will often be deficient of proper coating thickness; sharp edges should be rounded when possible with the National Association of Corrosion Engineers (NACE). A stripe coat or brush coat of primer prior to spray will assist in getting adequate coverage.
- **Nuts and bolts.** Premature coating failure and corrosion on nuts and bolt heads are common and can be reduced by conscientious surface

preparation prior to application of a protective coating. A brush coat of primer prior to spray will ensure adequate coverage.

- **Tube clamps.** Carbon steel clamps for interior applications are either zinc plated or painted. Stainless clamps shall be used for all exterior applications. Corrosion at the interface between the stainless steel tubing and the clamp can occur due to dissimilar metal and crevice corrosion. Corrosion at the interface between tubing and clamps is controlled by application of protective coatings.
- **Unistrut channels.** Use of unistrut channels should be avoided in exterior locations. When the exterior use of unistrut cannot be avoided, selection of appropriate material shall be utilized, such as stainless steel or fiber glass. Where corrosion is noted, mechanically clean the member to remove corrosion products followed by application of a zinc-rich coating.

Stainless Steel Components

General Stainless steel, although very corrosion resistant, is susceptible to localized corrosion (e.g., pitting, crevice corrosion, etc.) when exposed to marine environment. A mistake frequently made is to conclude that the corrosion noted on stainless steel tubing and bellows is only superficial. This conclusion is improperly reached when removal of external corrosion products leaves the surface in a condition that appears almost like new except for what appears to be a very tiny pit. A cross section taken through such a typical pit frequently discloses a void considerably greater in diameter than the surface pit diameter. Failure to arrest the apparent superficial corrosion will result in ultimate penetration of thin wall members.

Application of Protective Coatings

Stainless steel tubings shall be treated in the following way:

- Accumulated dirt and oil shall be removed by rinsing with water followed by rinsing with methyl ethyl ketone (MEK).

- Remove corrosion products by mechanical means, such as power tool cleaning or hand-tool cleaning.
- Clean surfaces with methyl ethyl ketone using clean rags.
- Apply by spraying, brushing, or dipping 75 μm (3 mils) minimum of the coating Aerocoat AR-7 manufactured by B.F. Goodrich.

Tubing assemblies shall be abrasive blasted. When tubing assemblies are in close proximity to carbon steel structural members that are to be abrasive blasted and coated with inorganic zinc-rich primer, the tubing assemblies shall be similarly treated.

- Using clean rags, accumulated dirt and oil shall be removed with water followed by wiping with methyl ethyl ketone.
- Apply a zinc-rich coating in accordance with the manufacturer's recommendations to a DFT (dry film thickness) of 100–150 μm (4–6 mils).

Cathodic Protection

Cathodic protection (CP) is a technique used to control the corrosion of a metal surface by making it the cathode of an electrochemical cell. CP is carried out by connecting the metal to be protected with a piece of another more easily corroded “sacrificial metal” to act as the anode of the electrochemical cell. The sacrificial metal then corrodes instead of the protected metal. For structures where passive galvanic CP is not adequate, like in long pipelines, an external DC electrical current is applied. Cathodic protection systems are used to protect a wide range of metallic structures in various environments. Common applications are steel water or fuel pipelines and storage tanks such as home water heaters, steel pier piles, ship and boat hulls, offshore oil platforms and onshore oil well casings, and metal reinforcement bars in concrete buildings and structures. A common application is in galvanized steel, in which a sacrificial coating of zinc on steel protects them from rust.

Cathodic protection can, in some cases, prevent stress corrosion cracking.

Applications Pipelines are routinely protected by a coating supplemented with cathodic protection. An *ICCP* – *impressed current cathodic protection* – system for a pipeline would consist of a DC power source, which is often an AC-powered rectifier and an anode, or array of anodes buried in the ground (the anode ground head)

Ships: cathodic protection on ships is often implemented by galvanic anodes attached to the hull, rather than using ICCP. Since ships are regularly removed from the water for inspections and maintenance, it is a simple task to replace the galvanic anodes. Galvanic anodes are generally shaped to reduced drag in the water and fitted flush to the hull to also try to minimize drag.

How to Prevent Metal Corrosion

- Choose products that are made of noncorrosive metals like stainless steel and aluminum.
- Maintain a dry environment using appropriate moisture barriers.
- Ensure the electrical connections are clean.
- On a car or truck, apply a thin coating of petroleum jelly after cleaning the terminal.
- Coat metals with oil, paint, grease, or varnish because it can prevent corrosion.
- Make use of cleaning agents like soaps, solvents, emulsion compounds, and chemicals to efficiently get rid of oil, grease, dirt, and other unwanted foreign deposits and follow the correct procedures in applying them.
- A mixture of cola and baking soda paste will remove metal corrosion on car batteries.
- To prevent soil corrosion, install correctly copper or copper alloy plumbing underground. The main causes of copper corrosion are poor drainage and moisture. A loose layer of backfill such as limestone or pea level must be put down in the trench before laying copper pipes.
- Galvanizing also provides metal corrosion protection. This is the process of giving a thin coating of zinc or steel material by immersing

the object in a bath primarily of molten zinc. Galvanizing is an efficient way to protect steel because even if the surface is scratched, the zinc still protects the underlying layer. This process is widely used in the auto industry.

Summary

Corrosion is effectively controlled by cathodic protection or by appropriate selection of inhibitors, provided the chemical and electrical conditions are scientifically monitored. Understanding of the mechanism is the key in handling the condition of the metals and structures. Every scenario is site specific and needs to be addressed on its associated factors of pH of the medium, environment, and temperature. Accordingly adopt the right protection techniques out of the available:

- Removal of oxidizing agent
- Prevention or inhibition of surface reaction
- Application of protective coatings – organic/metallic/nonmetallic
- Modification of the metal or the surface conditions

Co-sintering Method for Ceramic Membrane Preparation

Zhaoliang Cui

State Key Laboratory of Materials-Oriented Chemical Engineering, College of Chemistry and Chemical Engineering, Nanjing Tech University, Nanjing, China

Co-sintering method for ceramic membrane preparation. Conventionally, a multilayer ceramic membrane can be obtained by repeating the coating procedure. But the complicated, time- and energy-consuming production process, which generally comprises several sequential steps, induces high price. Obviously, reducing or combining steps is expected to cut production time and costs and thereby ceramic membrane price. As a method for fabrication of multilayer structures, the co-sintering process has attracted increasing attention due to simple preparation process and low production cost, including ceramic membranes (Lindqvist et al.) (Lindqvist and Liden 1997).

As shown in Fig. 1, in co-sintering process, a drying and a sintering step are eliminated, resulting in a faster and cheaper preparation. Another benefit of this process is the excellent linkage between the support and the intermediate layer, as well as the uniform and controlled thickness of the intermediate layer (Lindqvist et al.) (Lindqvist and Liden 1997). However, the thermal mismatch of each layer is a common and key problem during the co-sintering process. In a

Co-sintering Method for Ceramic Membrane Preparation,

Fig. 1 Co-sintering process (Feng et al. 2007a)

multilayer ceramic membrane, each membrane layer, which is made from ceramic powders with different compositions and particle sizes, exhibits different sintering behavior. Therefore, it is important to ensure the sufficient sintering of each membrane layer and also ensure the high bonding strength of each membrane layer in an asymmetric ceramic membrane (de Jong et al. 2004). For α -alumina membranes, too large shrinkage mismatch between two membrane layers, which occurs when co-sintering at 1,450 °C, causes many defects such as cracks and big pores. Moderate shrinkage mismatch existed when co-sintering at 1,300 °C, which can bring compressive stress in the sub-layer membrane, is beneficial to the whole co-sintering process (Feng et al. 2007a, b).

Cost-Effective Gas Separations

Pushpinder S. Puri

PuriMem, LLC, Emmaus, PA, USA

The separation of gases is an essential unit operation for a large number of chemical processes. The membrane-based gas separation processes are one of the several options available to the process engineers. Therefore, a membrane gas separation process has to compete with the more established gas separation processes such as cryogenic distillation, absorption, and adsorption. Although gas

separation membranes can be used for a wide range of applications, they have generally found their applications only in a few niche markets. These applications are listed in Table 1. In these markets membranes may not be the most cost-effective gas separation process but offer other advantages which make a compelling case for their use. These non-tangible benefits of the membrane gas separation processes are listed in Table 2.

Two necessary but not sufficient properties of the gas separation membranes are its selectivity for a given pair of gases and the gas permeation rate of the faster gas. The membrane selectivity is associated with the energy usage and/or product loss (energy cost), and the gas permeation rate is a measure of the membrane area needed (capital cost) for a given separation. Thus, these two factors have a major impact on the economic viability of a given membrane for a separation of interest. In addition, these two properties dictate the geometry of the membrane (tubular, hollow fiber or flat sheet), design of the membrane module, configuration of the membrane cascade (single stage or multiple stages), and process flow schemes (parallel, series, recycle, sweep, etc.) (Agrawal

and Xu 1996). They also determine the operational mode of the membrane such as pressurized feed gas with or without intermediate compression or membrane module operation with vacuum on the permeate side while keeping the feed gas a little over the atmospheric pressure. All these factors contribute to the bottom line economics of the gas separation process.

The life of the membrane and the replacement cost of the membrane module are a major contributor to the cost effectiveness of the membrane gas separation. For commercial membrane gas separations, the membrane life varies from application to application. A major contributor to the life of the membrane is its chemical compatibility with the feed gases. A membrane material may be chemically inert to the major gases in the feed gas, but the trace impurities present in it may damage the membrane over a period of time by causing compaction or other defects. In those cases, the feed gas may be pretreated to remove trace impurities before the gases are fed to the membrane separator. The type and extent of cleaning of the feed gases has a major bearing on the overall cost of gas separation by membranes.

Hybrid processes consisting of a membrane separation process with a conventional gas separation process sometimes offer a more cost-effective solution for gas separation. Two examples of these processes which are commercially used are in production of high purity nitrogen and in the treatment of natural gas. Air separation membranes have selectivity limitations; therefore, they are not best suited to produce high purity nitrogen. However, when a membrane air separation process is combined with an adsorption process, membrane separation produces 95–99 % nitrogen from which final traces of oxygen is removed by adsorption process (Choe et al. 1987). The second application of hybrid process is for the removal of acid gases from the natural gas. Here, a hybrid process consisting of acid gas selective membrane followed by an amine scrubbing process offers a more economical process for natural gas upgrading (Baker and Lokhandwala 2008).

Critical Flux

Xianhui Li and Jianxin Li
State Key Laboratory of Separation Membranes and Membrane Processes, School of Materials Science and Engineering, Tianjin Polytechnic University, Tianjin, China

The reduction in the permeate flux with time is a major problem in many pressure-driven membrane processes due to membrane fouling. This problem should be solved before the membrane processes are economically or technically viable. To control membrane fouling and maintain sustainable operation, the concept of critical flux was first introduced in 1995 (Field et al. 1995). The critical flux is defined as the flux below which flux decline with time does not occur, while fouling is observed above it. The supercritical flux fouling is ascribed to the fact that the convection of foulants toward the membrane by the permeate drag flow exceeds the back transport velocity of material from the membrane induced by shear and Brownian diffusion. Since then, the critical flux has been extensively applied to membrane processes from microfiltration (MF) to reverse osmosis (RO). Nowadays, the critical flux concept is well accepted by both scientists and engineers.

There are two forms of the critical flux: strong and weak form (Fig. 1a). In the strong form, the flux obtained during subcritical flux is equated to the clean water flux obtained under the same conditions. The strong form of critical flux is the point, at which the transmembrane pressure (TMP) starts to derive from the pure water line.

Critical Flux, Fig. 1 The strong and weak forms of critical flux (a) (Field et al. 1995) and critical flux measurement by the flux-step method (b) (Li et al. 2013)

In the alternative weak form, the flux–TMP relationship is below that of the pure water line, but increases linearly with pressure. The weak form of critical flux is the point at which this line becomes nonlinear. The difference between the two forms is that the strong and weak forms of critical flux are mainly caused by reversible and irreversible fouling, respectively. Therefore, the weak form of the critical flux is typically observed with the real effluents which contain many solutes of various molar masses.

However, the main drawback of this concept is that the determination of critical flux values cannot be theoretically predicted, but only experimentally measured by time-consuming experiments. The reason is that critical flux value is dependent on various factors, such as the characteristics of the membrane (pore diameter, porosity, and material), suspension system (nature, particle size distribution in relation to pore size distribution, and concentration), and the hydrodynamic and filtration conditions. Thus, a number of measurement methods for critical flux has been proposed (Table 1). The differences among these various methods are the quality (accuracy and reliability) and cost (length of experiment and complexity). The critical flux has mainly been obtained from flux–TMP measurements often by flux or pressure stepping (Fig. 1b). The mass balance method could be a useful complement for these methods with a determination of deposited mass. However, for complex suspensions, the analysis of the criticality via fouling rate has become increasingly common. Also the critical

Critical Flux, Table 1 Measurement methods for critical flux (Bacchin et al. 2006)

Methods	Advantages	Disadvantages	Suitability
Flux–pressure profile: deviation from linearity	Simplicity	Subjective and no link with reversibility	Feeds with low osmotic pressure
Flux or pressure vs. time: flux stepping	With up and down steps, fouling hysteresis found	Points of transition to irreversibility can be missed	Feeds with low osmotic pressure
Flux or pressure vs. time: flux cycling	Rigorous when allowance made for osmotic pressure	Time consuming and complex	All feeds
Direct observation through membrane (DOTM)	Direct observation of flux giving deposition	Soluble deposition not visible	Particulate feeds
Mass balance	Linked to complementary parameter, the deposited mass	Soluble deposition not visible	Particulate feeds
Determination by fouling rate analysis	Identify a point of sustainable flux	Subjective and no link with reversibility	All feeds

flux can be deduced from the observation of particle deposition (or their absence) on the membrane surface by direct observation through the membrane (DOTM). However, the industry system often operates at an acceptable fouling rate to achieve a higher permeability. The industrially acceptable flux is determined from economic considerations, and then its value would change as the balance between capital and running costs. Overall, the critical flux provides an important guide for the appropriate operating flux.

Cross-Flow Filtration

Xianhui Li and Jianxin Li

State Key Laboratory of Separation Membranes and Membrane Processes, School of Materials Science and Engineering, Tianjin Polytechnic University, Tianjin, China

The conventional pressure-driven membrane processes in liquid separation can be divided into two modes: dead-end filtration and cross-flow filtration. If there is no retentate stream, then the operation is termed “dead-end filtration.” If the retentate continuously flows from the module outlet, then the operation is termed “cross-flow filtration.” In the cross-flow filtration, the fluid feed stream runs tangential to the membrane surface, leading to a pressure differential across the membrane. This causes some of the particles to pass through the membrane. And the remaining particles continue to flow across the membrane. In contrast to the dead-end filtration technique, the

Cross-Flow Filtration,

Fig. 1 Schematic diagrams of cross-flow filtration (a) and representation of the steady filtration flow (b)

shearing effect caused by cross flow can sweep the deposited particles toward the concentrate or retentate side so that the cake layer remains relatively thin (Fig. 1a). In the case of cross-flow filtration, a cake layer will be built up gradually. After some time, a steady filtration state is obtained for a long time as shown in Fig. 1a. This fact is due to the equilibrium between the transport of particles to the cake layer and the back transport of particles into the feed stream. Consequently, the cross-flow filtration is commonly employed for the large-scale industrial membrane filtration process.

The permeate flux is governed by the general filtration equation (Darcy’s law) given as

$$J = \frac{\Delta P}{\mu \cdot R_h} \tag{1}$$

where J ($\text{m}^3/\text{m}^2/\text{s}$) is the permeate flux, ΔP (Pa) is the applied pressure, μ (Pa.s) is the solvent viscosity, and R_h (m^{-1}) is the hydraulic resistance.

Certainly, many parameters of cross-flow filtration play a key role in filtration performance. As summarized in Table 1, the parameters influencing filtration performance cover hydrodynamics and operating conditions, membrane characteristics, as well as the fluid characteristics. For example, on the basis of Darcy’s law, the operating conditions (transmembrane pressure, cross flow, and temperature) are directly related to the permeate flux. Membrane characteristics (pore size, surface free energy, hydrophilicity/hydrophobicity, etc.) and fluid characteristics (pH,

particle size, interactions, etc.) will strongly impact the physicochemical interactions that occur between the fluid constituents and the membrane surface as well as between these constituents. Therefore, the goal of membrane technologists is to use appropriate membrane material, module configuration, system design, and operating conditions to achieve the most economical process.

Cross-Flow Filtration, Table 1 Summary of the parameters influencing cross-flow filtration performance (Rayess et al. 2011)

	Parameters
Operating conditions	Transmembrane pressure, permeate flux, cross-flow velocity, and temperature
Membrane characteristics	Pore size, porosity, hydrophilicity/hydrophobicity character, and surface free energy
Fluid characteristics	Physicochemical interactions (electrostatic, polar, etc.), pH, ionic strength, suspension concentration, and suspension size

In order to apply membranes in a technical scale, large membrane areas normally are required. The smallest unit into which a membrane area is packed is called a module (Mulder 1997). The earliest designs were based on simple filtration technology and consisted of flat sheets of membrane held in a type of filter press (Baker 2004). Modules containing only one membrane, which are mostly used in laboratory scale, are cross-flow membrane modules. If several membranes are

used, these modules are called plate and frame modules.

Cross-Link

Zhi Wang

Chemical Engineering Research Center, School of Chemical Engineering and Technology, Tianjin University, Tianjin, China

The reticulate polymer formation processes by the interactions of linear or branched polymer chains using the chemical modification or physical modification are defined as “cross-link.” Cross-link is mainly divided into two types including chemical cross-link such as polycondensation or polyaddition cross-link (Beryozkina et al. 2009; Luis et al. 2012) and physical cross-link such as heat or photo cross-link (Chujo 2010; Farrell et al. 2005). Chemical cross-link is defined as the interaction process of linear or branched polymer chains by using the covalent bond among the functional groups of the polymers and cross-linking agents. Most of the chemical cross-linking agents are small molecular compounds with the molecular weight of 200–400, which have two or more functional groups such as amine group (Bernardo et al. 2009). Physical cross-link is the interaction process of linear or branched polymer chains by using the physical interaction such as van der Waals forces and hydrogen bond among the functional groups of the polymers and cross-linking agents. After cross-linking, polymer properties such as the mechanical strength, elasticity, solvent resistance, and permeate selectivity could be improved (Bernardo et al. 2009; Beryozkina et al. 2009; Chujo 2010; Farrell et al. 2005; Luis et al. 2012).

In the membrane fabrication process, cross-link is also mainly divided into two types including chemical cross-link and physical cross-link. Hydrogen bond cross-link is a special physical cross-link. Different from other cross-links, the functional groups of the polymer will be not depletion after the hydrogen bond cross-link (Basu et al. 2010). Compared with the covalent bond, the hydrogen bond energy is smaller, and the bond length is longer, which is a weak link. However, a large amount of hydrogen bonds can stably exist in the membrane at low pressure due to the strong physical interactions (Basu et al. 2010). In the membrane fabrication process, chemical cross-link and physical cross-link often make the gap space between the polymer chain segments smaller and limit the vibration of the polymer chain segment, which are main ways to improve the selectivity (rejection) of the permeate (Luis et al. 2012; Zhao et al. 2006; Basu et al. 2010; Qiao et al. 2013; Kim et al. 2000). However, most of the cross-linking processes will make the membrane structure densification and may be not favorable for the permeance (flux) increase of the permeate in the membrane process (Luis et al. 2012; Basu et al. 2010; Zhao et al. 2006). Fortunately, in the recent studies, the cross-linking agents with functional groups such as amine group used to modify the polymer could simultaneously improve the selectivity and permeance of the permeate in the gas separation membrane process (Qiao et al. 2013).

Cross-Linkable Copolymer Membranes

Zhi Wang

Chemical Engineering Research Center, School of Chemical Engineering and Technology, Tianjin University, Tianjin, China

Cross-linkable copolymer membrane is one of the most extensively used polymeric membranes, such as gas separation membrane, pervaporation membrane, proton exchange membrane for fuel cell, and stimuli-responsive membrane.

Cross-linkable copolymer is a kind of copolymer bearing the cross-linkable groups in the chain end or the side-chain of one specific unit. Amino group, epoxy group, carboxyl group, silane group, and vinyl group are the common cross-linkable groups. Furthermore, some specific cross-linkable groups could be incorporated in the copolymer matrix in terms of actual demands. Cross-linking reaction can be carried out through thermal/photo initiation by oneself or chemical reaction with other cross-linking reagents. Various properties of copolymer such as thermal stability, mechanical strength, and chemical resistance could be improved after cross-linking. As a novel polymeric material, cross-linkable copolymers are widely used for fabrication of stimuli-responsive polymer vesicles (Li and Keller 2009) and organic

light-emitting diodes (Segalman et al. 2009). Moreover, cross-linkable copolymers are the favorable polymeric membrane materials owing to their diversity.

Cross-linkable copolymer membranes exhibit the characteristics of structure control and property tunability due to the versatility of comonomers and cross-linkable groups of cross-linkable copolymers. Cross-linkable copolyimide is a class of fine membrane materials for CO₂ separation. Most of the glassy polymers suffer from CO₂-induced plasticization at high CO₂ partial pressure (Bos et al. 1999). However, cross-linked copolyimide reveals excellent CO₂ plasticization resistance due to the formation of rigid polymer networks (Vanherk et al. 2013). End-group cross-linkable sulfonated copolymers (poly(arylene ether ketone), poly(ether ether ketone), etc.) are the predominant proton exchange membrane materials for fuel cell, which often provide improved proton conductivity and reduced water uptake via proper cross-linking (Jones and Roziere 2009). Cross-linkable copolymers with different functional comonomers are the primary sources of stimuli-responsive membrane. Stimuli-responsive membranes have an extensive application of drug controlled release and sensors/actuators for different stimuli (temperature, light, thermal, pH, etc.) (Qiu and Park 2012). Furthermore, another decided advantage of cross-linkable copolymer membrane is their exceptional thermal, mechanical, and chemical stability after cross-linking reaction, which provides a solid fundament for practical applications in harsh environment.

An increasing number of novel cross-linkable copolymers will be developed with the progress of polymer chemistry. Therefore, they will have broad application prospects in membrane science and technology.

Cross-Linked Aromatic Polyamide Membranes

Zhi Wang

Chemical Engineering Research Center, School of Chemical Engineering and Technology, Tianjin University, Tianjin, China

Cross-linked aromatic polyamide membranes are, typically, the aromatic polyamide-based thin film composite membranes. Aromatic polyamides are macromolecules with repeating units linked by amide bonds, which are produced from the

condensation reaction of the aromatic amino groups and the aromatic carboxylic acid or acid chloride groups (Palmer 2002). Aromatic polyamide fibers, which have high resistance to abrasion, low flammability, and excellent mechanical properties, are widely used in aerospace and military applications. Moreover, aromatic polyamide is also one of the best membrane materials, which can form dense cross-linked aromatic polyamide membranes via interfacial polymerization processes.

The cross-linked polyamide membranes are, usually, used as brackish water or seawater desalination membranes, such as reverse osmosis (RO), forward osmosis (FO), and nanofiltration membranes. Cross-linked aromatic polyamide RO membranes, derived from metaphenylene diamine (MPD) and trimesoyl chloride (TMC), are the most widely used commercial reverse osmosis membranes. The structure of the membrane is shown in Fig. 1. This partially cross-linked chemical structure consists of the cross-linked portions ($C_{18}H_{12}N_3O_3$) and the linear portions ($C_{15}H_{10}N_2O_4$) (Wei et al. 2010). The commercial cross-linked aromatic polyamide RO membranes always exhibit superior water flux and salt rejection, resistance to pressure

Cross-Linked Aromatic Polyamide Membranes, Fig. 1 The barrier layer structure of the cross-linked polyamide RO membrane

compaction, wider operating temperature range and pH range, and higher stability to biological attack, compared with cellulose acetate RO membranes (Li and Wang 2010). Currently, there are kinds of commercial cross-linked polyamide RO membranes, produced by some leading membrane manufacturing companies, such as Dow (Filmtec™), Hydranautics, Toray, GE Osmonics (Desal), and Koch Membrane Systems (Fluid Systems™).

However, the cross-linked aromatic polyamide membranes, including RO, FO, and nanofiltration membranes, have some problems to be solved. The first is the membrane fouling due to its high pollutant deposition tendency (Subramani and Hoek 2010). Membrane fouling, which is a process that the solutes, particles, and bacterium deposit on the membrane surfaces, can cause flux decline and affect the quality of the water produced (Kang and Cao 2012). The second problem is that the chlorine resistance of the membranes needs to be improved compared with cellulose acetate RO membranes (Kang et al. 2007). This is because the amide bonds can be easily halogenated by the free chlorine in the feed solution, resulting in the degradation of the membranes.

Cross-Linked Layer-by-Layer Membranes

Saren Qi¹ and Chuyang Y. Tang²

¹Singapore Membrane Technology Centre, Nanyang Technological University, Singapore, Singapore

²Department of Civil Engineering, The University of Hong Kong, Hong Kong, Hong Kong SAR

A layer-by-layer (LbL) membrane is formed by coating a porous substrate with polyanions and polycations in an alternative sequence (Decher 1997). Because of the electrostatic forces between the charged polymers, the polyanions and polycations are self-assembled into thin layers. Advantages of LbL membranes include its controllable structure and composition as well as facile process of fabrication and modification. LbL membranes are able to reject a variety of contaminants including divalent ions. Their rejection of monovalent ions tends to be relatively low, but can be potentially improved by posttreatment.

Cross-linking is commonly used to treat LbL membranes for improved rejection and enhanced membrane stability (Qiu et al. 2011). The selective multilayers (the rejection layers) of LbL membrane are mainly formed by the electrostatic interaction that is weaker than covalent bonds. Therefore, the stability of LbL membranes is a key concern in their applications, particularly when the feedwater has high ionic strength that weakens the ionic bonds. The cross-linking treatment offers an effective solution to this problem. The commonly used cross-linking method includes chemical cross-linking (with the help of cross-linking agents such as terephthalaldehyde and glutaraldehyde) (Qi et al. 2012), UV-assisted cross-linking (Duong et al. 2013), and heat-induced cross-linking (Dai et al. 2001). The resultant cross-linked LbL membranes exhibit improved rejection, good chemical resistance, mechanical strength, and long-term stability.

LbL membranes can be classified according to their applications. The common application fields include water treatment (Bruening et al. 2008),

Cross-Linked Layer-by-Layer Membranes,

Fig. 1 Schematic diagram of applications for LbL membrane (Note: *NF* nanofiltration, *FO* forward osmosis, *UF* ultrafiltration, *MF* microfiltration)

pervaporation (Zhao et al. 2011), and fuel cell (Zhang and Shen 2012) (Fig. 1). In water treatment process, LbL membranes present high water permeability and relatively good salt rejection. It is because ultrathin multilayers can achieve high water permeability and dense multilayers can maintain membrane selectivity. On the other hand, LbL membranes usually bring charges that may enhance the rejection due to Donnan exclusion. Additionally, due to the availability of functional groups in polyelectrolyte molecules, LbL method is easily incorporated with other technologies to produce new functional membrane. For example, Ag nanoparticles can be incorporated into LbL FO membrane to produce a novel FO membrane for antibacterials (Liu et al. 2013). In pervaporation, LbL membranes used can produce high permeate flux due to its ultrathin layers, and the selective layer is resistant to organic solvent. In fuel cell, compared with traditional process of fabrication (i.e., spraying, painting, ink-jet printing, and so on), more efficient process could be achieved by using LbL membrane for proton transfer. Additionally, while incorporated with other materials, LbL membranes can increase the catalyst utilization rate so as to enhance the fuel cell performance.

Cross-Linked Poly(ethylene oxide) Membranes

Haiqing Lin

Department of Chemical and Biological Engineering, University at Buffalo, The State University of New York, Buffalo, NY, USA

Poly(ethylene oxide) (PEO) and its containing polymers have been extensively explored as membrane materials for CO₂ removal from the mixtures with light gases such as hydrogen, nitrogen, and methane (Blume and Pinnau 1990; Li et al. 1995; Okamoto et al. 1995; Bondar et al. 1999, 2000; Hirayama et al. 1999; Yoshino et al. 2000; Kim et al. 2001; Patel et al. 2003, 2004; Lin and Freeman 2004, 2005; Metz et al. 2004; Lin et al. 2006a, b, c; Car et al. 2008; Reijerkerk et al. 2010; Yave et al. 2010; Lau et al. 2011; Liu et al. 2013). The polar ether oxygen has strong affinity with CO₂ with quadrupole moment, but not with light gases, thus providing high CO₂ solubility and high solubility selectivity of CO₂/light gas (Okamoto et al. 1995; Bondar et al. 1999; Lin and Freeman 2004). On the other hand, unlike any other polar groups which would inevitably increase the chain rigidity of the polymer and decrease CO₂ diffusivity and permeability, ether oxygens appear to be the only well-known groups which improve CO₂ diffusivity and permeability (Lin and Freeman 2005; Lin et al. 2006c). Ethylene oxide units have a high concentration of ether oxygens, which makes the ideal as building blocks for membrane materials for CO₂/light gas separation. However, PEO has high crystallinity which is deleterious for gas permeability (Lin and Freeman 2005).

Cross-linking is an effective way to inhibit polymer chain crystallization (Hirayama et al. 1999). Graham proposed empirically that significant crystallinity in cross-linked PEO is not evident when the molecular weight between cross-links is lower than 1,500 (Graham 1987). Cross-linking can be achieved by radiation or radical cross-linking of high molecular weight

PEO or by reactions of end groups such as hydroxyl or vinyl groups. Hirayama et al. prepared cross-linked PEO from mixtures of poly(ethylene glycol) methacrylate (a monomer containing nine EO units) and poly(ethylene glycol) dimethacrylate (a cross-linker containing 14 EO units) by plasma irradiation (Hirayama et al. 1999). They reported that CO₂ permeability increases as monomer content increases while CO₂/N₂ selectivity remains almost unchanged. They prepared a polymer containing 70 wt% monomer; it exhibited a CO₂ permeability of 260 Barrers and a CO₂/N₂ selectivity of about 48 at 35 °C and 1 atm (Hirayama et al. 1999).

Several series of cross-linked PEO have been prepared by UV photopolymerization of poly(ethylene glycol) diacrylate (PEGDA) containing 14 EO units and poly(ethylene glycol) methyl ether acrylate (PEGMEA) containing about 8.5 EO units (Lin and Freeman 2005; Lin et al. 2006a, c). The resulting chemical structure is shown in Fig. 1 (Kalakkunnath et al. 2005, 2006). PEO crystallinity was completely absent in these copolymers at temperatures as low as −90 °C (the lowest limit of the calorimeter used) due, presumably, to the short nature of the EO branches in the side chains of these materials and to the frustration of crystallization by cross-linking. The average number of EO units per acrylate group is approximately seven, which is the minimum number of monomers required for the unit cell of a PEO crystal (Brandrup et al. 1999). Therefore, using these starting materials, network polymers can be prepared which are noncrystalline and have a high concentration of EO units. The use of acrylate groups instead of methacrylate groups provides higher chain flexibility (or lower glass transition temperature), which can increase gas diffusion coefficients and, in turn, permeability (van Amerongen 1964; Lin et al. 2005).

The inclusion of methyl ether chain end groups in the monomer (as opposed to hydroxyl end groups) increases free volume and improves CO₂/H₂ separation performance of copolymers of PEGMEA and PEGDA. As PEGMEA monomer content increases from zero to 99 wt%, CO₂

Cross-Linked Poly(ethylene oxide)

Membranes,

Fig. 1 Schematic representation of PEGDA/PEGMEA copolymer network (Kalakkunnath et al. 2005, 2006). Italicized and bolded parts of the network derive from the cross-linker. R1 is CO (OCH₂CH₂)₈OCH₃ from PEGMEA; R2 is COO (CH₂CH₂O)₁₄OC from PEGDA

Cross-Linked Poly(ethylene oxide)

Membranes,

Fig. 2 Comparison of cross-linked poly(ethylene oxide) membrane with other polymeric membranes in the literature used for CO₂/H₂ separation (Lin et al. 2006a)

permeability increases about fourfold, reaching 570 Barrers, and CO₂/H₂ selectivity increases by 50 %, up to 12, at 35 °C and infinite dilution (Lin et al. 2006). These materials show good CO₂/H₂ separation properties, as shown in Fig. 2. If the -OCH₃ end groups are replaced by -OH end groups, CO₂ permeability and CO₂/H₂ selectivity remain unchanged as the -OH end group content changes across the entire composition window (Lin et al. 2006c).

In general, the cross-linked network materials formed from PEG acrylates and diacrylates provide advantages for CO₂/light gas separation

performance, compared with other PEG-containing polymers such as block copolymers (Lin and Freeman 2006).

1. Cross-linking ensures good chemical resistance, simply because cross-linked networks are not soluble. It is straightforward to incorporate more than 80 wt% PEO in cross-linked polymers from acrylate monomers and/or cross-linkers, which is higher than the maximum value (about 60 %) reported for block copolymers and blends (Okamoto et al. 1995; Yoshino et al. 2000).

2. Cross-linked PEO can be further modified to give much higher CO₂ permeability and CO₂/H₂ selectivity than block copolymers or blends by introducing methyl ether chain end groups (Hirayama et al. 1999; Lin et al. 2006a, c).
3. Finally, cross-linking could completely suppress crystallization at all temperatures of practical interest (Lin et al. 2006c), while block copolymers or blends would still exhibit a melting temperature at temperatures near ambient (Bondar et al. 1999). Consequently, with the cross-linked PEO materials, temperature can be lowered to optimize CO₂ separation performance because lower temperatures favor CO₂/light gas solubility selectivity (Lin et al. 2006a, c).

Cross-Linked Polyamide Membranes

Zhi Wang

Chemical Engineering Research Center, School of Chemical Engineering and Technology, Tianjin University, Tianjin, China

The cross-linked polyamide membrane is one of the most commonly used polymeric membranes for nanofiltration (NF), reverse osmosis (RO), forward osmosis (FO), pervaporation (PV), and gas separation (GS).

The polyamide could be produced either naturally or artificially. The natural polyamides include proteins and peptides. The artificial polyamides, such as nylons and aramids, could be produced by polymerization. Polyamides are widely used in textiles, automobiles, and carpet due to their extreme durability and strength. Moreover, polyamides possess excellent separation property and are promising materials for separation membranes.

The cross-linked polyamide membrane is usually thin-film composite (TFC) membrane consisting of a dense top layer of cross-linked polyamide with a thickness of 0.1–0.3 μm supported by a sublayer with a thickness of 50–150 μm . The membrane is generally fabricated by interfacial polymerization (IP) of di- or multi-amines in aqueous phase and di- or multi-acyl chloride in organic phase on the sublayer. Various diamines have been used to fabricate

membranes for different applications, for example, piperazine (PIP) for NF; m-phenylenediamine (MPD) for RO, FO, and PV; and 3,3'-diamino-N-methyldipropylamine (DNMDAm) for GS (Petersen 1993; Chapman et al. 2008; Lau et al. 2012; Zhao et al. 2012; Li et al. 2012). Trimesoyl chloride (TMC) is the most widely used acyl chloride in IP. The three reactive acyl chloride groups of TMC could form the cross-linked structure that potentially enhances both separation performance and mechanical strength of the membrane. The reaction between these two reactive monomers, i.e., diamine and TMC, is shown in Fig. 1. The formed polyamide contains both cross-linked structure and linear structure. The linear structure is caused by the hydrolysis of acyl chloride group. The ratio of cross-linked part to linear part of the polyamide, as well as the surface characteristic and the thickness of polyamide layer, could be finely adjusted by changing technological parameters of IP process, such as solvent type, monomer concentrations, reaction time, and posttreatment conditions. The performance of the membrane therefore could be improved by optimizing the structures.

The cross-linked polyamide membranes for NF and RO in applications of desalination have been successfully commercialized for decades. There are several membrane suppliers providing NF and RO membranes for large-scale desalination plants, such as DOW, Toray, Hydranautics, and Toyobo. The salt rejection and water permeability of NF and RO membranes have been drastically improved during these years but the

Cross-Linked Polyamide Membranes, Fig. 1 Reaction scheme for preparation of cross-linked polyamide membranes by IP

antifouling and chlorine resistant properties of the membranes still have to be enhanced (Xu et al. 2013). The cross-linked polyamide membranes for FO in applications of desalination are still in laboratory research due to the challenges of concentration polarization, fouling, and reverse solute diffusion (Zhao et al. 2012). The cross-linked polyamide membranes for PV in applications of dehydration and for GS in applications of CO₂ separation are fabricated in laboratory scale at present, because the permeance and selectivity of membranes have to be improved to fulfill technical and economical requirements of practical applications. The improvement of separation performance of membranes for GS could be achieved by combining multiple separation mechanisms into a single membrane through selecting proper monomers in IP process (Li et al. 2012).

Crown Ethers

P. K. Mohapatra
Radiochemistry Division, Bhabha Atomic
Research Centre, Mumbai, Maharashtra, India

Pedersen (1967) synthesized the crown ethers (see Fig. 1a) for the first time in 1967 which formed

stable complexes with alkali/alkaline earth metal ions and displayed a unique selectivity based on the size compatibility of the ligand cavity size and the ionic size of these metal ions. The crown ethers mimic the biological receptors such as valinomycin (see Fig. 1b) which selectively transports K⁺ ion as compared to Na⁺ ion (by a factor of 10⁵) across cell membranes. The transport properties of the crown ethers depend on the size of the crown ring, number of donor atoms, nature of donor atoms, nature of lipophilic/ionizable side arms, etc. Crown ethers have been overwhelmingly used for the transport of alkali metal/alkaline earth ions, though there have been quite a large number of reports on the transport of Ag⁺, Hg²⁺ (with thia-crown ethers), and Pb²⁺ which are proposed for heavy metal removal from wastewaters (Lamb et al. 1980). There have also been several reports on the use of crown ethers for the selective transport of lanthanides and actinides though size selective factors are far less pronounced in such cases. Another major application of crown ethers for metal ion transport includes the recovery of radio-caesium and radio-strontium from radioactive wastes which can significantly reduce the load on the vitrified glass blocks (Dozol et al. 1995; Dozol and Casas 1994). Crown ether-based supported liquid membranes have shown large amounts of acid cotransport when attempts have been made for the transport of Cs-137 and Sr-90 from nitric acid feeds. This has affected the overall efficiency of the transport process, and appropriate selection of the diluent has helped in overcoming this issue (Raut et al. 2012). Though crown ethers have been employed for the transport of Cs(I) in laboratory-scale studies, calix crowns (where crown ether structure has been appended to a calix[4]arene) have been proposed as one of the most efficient carrier extractants for the effective transport of radio-caesium (Casnati et al. 1995). Transport of organic/biological receptors like cytochrome C (Paul et al. 2003) and amino acids (Yamaguchi et al. 1988) has also been facilitated by crown ethers.

Usually, the neutral macrocyclic ionophores like crown ether, cryptand, calixarenes, cavitands, etc. require a large lipophilic counter anion like

Crown Ethers, Fig. 1 Structural formulae of (a) a typical crown ether, (b) valinomycin, and (c) an ionizable lariat crown ether

picrate, tetraphenyl borate, etc. for the effective transport of the cationic species from the aqueous phase to the membrane phase. The ion pairs are subsequently transported across the membrane phase which usually contains a polar diluent such as chloroform, long-chain alcohols, ethers, etc. for the stabilization of the charged metal-carrier (crown ether) complex. However, the large molar volume counter anions can make the diffusion of the ion pair rather slow. Appending an ionizable pendent arm to the crown ether ring (the ligand is called an ionizable lariat ether; see Fig. 1c) can eliminate the need for the counter anions making it a more efficient transport system (Strzelbicki et al. 1989). Other types of functionalization have been found to impart exotic properties to the receptors. For example, crown ethers with suitable functional groups based on redox-switched (Shinkai et al. 1985a), thermosensitive (Shinkai et al. 1985b), and photoresponsive (Shinkai et al. 1981) properties have also been used for the transport of receptors. Functionalized crown ether-type ligands with carboxylate groups have been suggested for the recovery of U from seawater which is yet another exotic application of the crown ether-based membrane transport systems.

Cryogels

Nilay Bereli, Handan Yavuz and Adil Denizli
Department of Chemistry, Biochemistry Division,
Hacettepe University, Ankara, Turkey

Chromatography is the most powerful technology in the downstream applications for the separation of proteins both in the analytical and large scale. Conventional packed bed columns have been used for many applications; however, they have some important drawbacks such as the slow diffusional mass transfer and the large void volume between the beads (Gun'ko et al. 2013). In order to resolve these problems, nonporous beads and perfusion chromatography packing have been designed and used as a carrier, but these adsorbents are not sufficient to resolve these limitations in essence. New-generation stationary phases i.e.,

polymeric cryogels, are found to have an increasing use in the separation science due to their easy preparations, excellent flow properties, and high performances compared with the conventional beads. Cryogels are mega-porous three-dimensional networks formed under freezing conditions. The pore size of the cryogels varies from 10 to 250 μm (Fig. 1), which can be changed by optimizing the freezing regime and type and concentrations of polymerization precursors. The unique properties of cryogels like osmotic, chemical, and mechanical stability, large pores, short diffusion path, low-pressure drop (Fig. 2), and short residence time for both binding and elution stages make them attractive matrices for affinity chromatography of large molecules such as proteins, plasmids even whole cells, as well as small molecules (Lozinsky et al. 2001; Stela and Valentina 2013; Bereli et al. 2008, 2010; Tamahkar et al. 2011; Derazshamshir et al. 2010). Therefore, cryogels can be used in the various affinity chromatography applications such as protein A affinity chromatography, histidine affinity chromatography, thiophilic affinity chromatography, metal-chelate affinity chromatography, dye affinity chromatography, ion-exchange chromatography, DNA affinity chromatography, cell affinity chromatography, molecular imprinting technique, etc.

Crystal Grow

Benny Danilo Belviso

Istituto di Cristallografia, Consiglio Nazionale delle Ricerche (C.N.R.), Bari, Italy

Crystal growth is the second stage of the crystallization process and consists in the addition of

new atoms, ions, molecules, or polymer strings on preformed crystalline nuclei coming from the nucleation stage. The result of the crystal growth is the formation of a crystalline solid, whose atoms are reciprocally fixed in the space according to the symmetry rules characteristic of the space group in which the growth takes place. Similarly to crystal nucleation, crystal growth requires that the concentration of the solute is in the supersaturation range (metastable zone): when supersaturation is reached, the number of molecules that attach the crystal surface exceeds that of the molecules that detach, leading to an increase of crystal dimension. The strength of bonding formed between the crystal surface and the new molecules depends on the temperature rather than the concentration of the solute. Accordingly, crystal growth requires a lower supersaturation level than that required for nucleation stage; however, too low supersaturation can result in the crystal dissolution. Traditionally, crystal growth is divided in two distinct phases: (a) transfer of mass from the crystallizing solution to the crystal/solution interface, which is governed by diffusion and convection mechanisms, and (b) the attachment of molecules on the preformed crystal. Crystal surface consists of flat regions (terraces), raised layers (steps), islands, and kinks (Fig. 1a), each having different abilities to interact with new molecules from the bulk of the solution. Differently from the flat surfaces, kinks are the most suitable sites to promote crystal growth, since the presence of adjacent walls to which new molecules can attach allows reducing the activation energy to incorporate new molecules (Chernov 1984). In the presence of high density of kinks, crystal growth occurs in spiral fashion around the single kinks and expands by rotating around the emergence of the screw dislocation (screw dislocation mechanism) (Fig. 1b). Differently, in the case of crystals with perfectly flat faces, the molecules coming from solution tend to form two-dimensional layers on the surface due to the lack of suitable attachment points to bind the crystal surface. The mechanism is slow and requires high supersaturation. In both cases, the increase of crystal dimension stops when the density of impurities on the surface of the crystal

Crystal Grow, Fig. 1 Crystal growth process. (a) The molecule of solute binds to the kink site after adsorbing and diffusing across the terraces. (b) Geometry of a screw dislocation. The existence of a critical size leads to the

formation of the spiral structure (growth direction in *red line*), since the new segment of the step cannot move until it reaches that size

reaches a critical value able to poison the process (Durbin and Feher 1990). Quality of the crystals strictly depends on the supersaturation level and, hence, on the ratio between the rate of nucleation and crystal growth: while a low level of supersaturation favors the crystal growth and slowly leads to few large crystals usually having high quality (Frank 1949), higher supersaturation supports an excess of nucleation and leads to a rain of small crystals. The use of membranes as dosing devices to modulate the solvent removal from the crystallizing solution by varying process parameters and membrane features makes possible the control of the extent both of nucleation and of crystal growth: variations able to increase the supersaturation stimulate the nucleation at the expenses of crystal growth, while variations influencing the transmembrane flux can slow the achieving of the supersaturation, encouraging the crystal growth over nucleation. It follows that crystals appear after more time, but they are larger and usually of high quality (Curcio et al. 2003; Zhang et al. 2008). In addition, the use of membrane devices as active supports of crystallization allows to induce the nucleation and crystal growth stages in separate sites. This reduces the risk of membrane fouling, even when the same membrane supports heterogeneous nucleation, and allows to fully exploit the advantages coming from heterogeneous nucleation and growth at low supersaturation, leading to a great production of large crystals.

Crystal Nucleation

Benny Danilo Belviso
Istituto di Cristallografia, Consiglio Nazionale
delle Ricerche (C.N.R.), Bari, Italy

Crystal nucleation is the first stage of a crystallization process and leads to the formation of distinct crystal nuclei. It is a local phenomenon of aggregation, and it is said to be homogeneous when it occurs in the bulk of the solution and

Crystal Nucleation,

Fig. 1 Effect of the nucleus radius (r) on the free energy of germination ΔG_g (in black color). Interfacial free energy and free energy of aggregation are reported in red and green color, respectively

heterogeneous on very small solid particles, such as amorphous clusters or crystalline particles. In both cases, the formation of crystal nuclei requires well-oriented collisions between molecules to occur. The activation energy necessary to induce nucleation is represented by the free energy of germination $\Delta(G_g)$ shown in Eq. 1 (Mullin 1972), consisting of a positive term called interfacial free energy (in red color in Fig. 1) and a negative term called free energy of aggregation (in green color in Fig. 1):

$$\Delta G_g = 4\pi\rho r^2 - ((4\pi r^3)SkT)/3V \quad (1)$$

In the Eq. 1, V is the volume of the molecule to crystallize, ρ is the interfacial free energy, T is the temperature, k is the Boltzmann factor, and r is the average radius of the crystal nuclei. ΔG_g reaches a maximum value for a given nucleus radius (Fig. 1); therefore, only crystal nuclei that grow up to this dimension are stable, while smaller nuclei dissolve before to pass the next crystal growth. In order to reduce the energy of activation, high S value, that is an estimation of the supersaturation level of the solution, is required. Supersaturation is an essential condition required during each stage of the crystallization process; however, the nucleation, being the most energy expensive stage of the entire crystallization process, requires higher supersaturation level to take

place. The mechanism and the rate of nucleation strongly influence quality and quantity of the produced crystals; therefore, many efforts are devoted to control the nucleation in order to obtain crystals having high quality. One of the main problems in industrial or laboratory crystallization processes is the excess of nucleation that usually leads to a rain of tiny poor-quality crystals. The use of filtered solutions is the solution commonly adopted to overcome this problem; however, in the cases where nucleation is welcome, the presence of dust or small foreign particles, such as mica or silica able to promote heterogeneous nucleation, can represent an advantage (Falini et al. 2002; Saridakis and Chayen 2009). These particles, also called crystallization seeds, act as nucleant and usually increase the chances of crystallization by facilitating the proper molecular orientation during the formation of the crystal nuclei (Bolanos-Garcia and Chayen 2009). The result is the reduction of the activation energy and, consequently, the decrease of the supersaturation level required to induce the formation of crystal nuclei with respect to that required in the homogeneous nucleation. In these conditions, nucleation could even occur in the metastable zone where crystals grow larger and better ordered than those grown at higher supersaturation level. The direct contact between crystallizing solution and an irregular surface can induce heterogeneous

nucleation, as occurs in membrane crystallizers (Di Profio et al. 2003, 2005). The local entrapping of the solute molecules in the pores of the membrane causes an increase of the local level of supersaturation (Curcio et al. 2006), inducing the

Crystal Nucleation, Fig. 2 Mechanism of crystal nucleation on membrane. Solute molecules (*red spheres*) are adsorbed on the surface and are trapped inside the pores of the membrane, resulting in an increase of local concentration

formation of crystal nuclei also in the presence of lower amount of initial substance. For this reason, membrane crystallizers are particularly attractive for crystallization processes where the solute is expensive, such as in the case of proteins. In addition, a fine regulation of the nucleation rate can be achieved by managing the transmembrane flux of the solvent from the crystallizing solution toward the stripping solution located on the other side of the membrane. Nucleation mechanism on the membrane (Fig. 2) consists of a first phase where solute molecules are adsorbed on the surface by means of attractive interactions able to properly orient the molecule and that usually drive the growth of the crystal toward a specific crystal structure (Di Profio et al. 2009). The effective control of the nucleation process by means of an appropriate choice of the porosity and hydrophobicity of the membrane and by managing the transmembrane flux makes membrane crystallizers particularly suitable for industrial applications.

Crystal Polymorphism

Polymorphism

Benny Danilo Belviso

Istituto di Cristallografia, Consiglio Nazionale delle Ricerche (C.N.R.), Bari, Italy

The term polymorphism comes from the Greek word *polus* = many and *morph* = shape, and it is the propriety of the chemical substances to exist in more crystal forms, each having a specific arrangement of atoms or ions in the crystal lattice. Crystal polymorphism includes the allotropy

phenomenon, which refers to pure elements. Crystal forms that differ for packing or for molecular conformation are said packing or conformational polymorphs, respectively. From a thermodynamic viewpoint, polymorphism can be of two kinds: enantiotropic (Fig. 1a), in the case of crystal forms stable in a precise range of temperature and pressure (e.g., the system rhombic sulfur-monoclinic sulfur in Fig. 1b), and monotropic (Fig. 1c), in the case of crystallization process that spontaneously evolves toward a crystal form characterized by lower internal energy with respect to the other forms (metastable forms). Generally, monotropes and enantiotropes can be recognized by their heats of fusion, since monotropes come from exothermic processes and

Crystal Polymorphism, Fig. 1 Enantiotropic and monotropic systems. (a) Variation of free energy with temperature for enantiotropic substances. The temperature T_x , which marks the boundary between stability zones for A and B forms, is below the melting temperatures of the two substances (T_A^m and T_B^m). (b) Phase diagram for the

enantiotropic system rhombic sulfur-monoclinic sulfur. (c) Variation of free energy with temperature for enantiotropic substances. No crossing of free energy curves belonging to the A and B forms can be observed below of their melting temperatures (T_A^m and T_B^m)

enantiotropes from endothermic processes. Whatever is the kind of polymorphism, under static crystallization conditions, the probability of carrying out crystallization precisely at the boundary that separates the polymorphic forms is small; therefore only one crystal form appears at the end of the crystal growth. The mechanism that explains the polymorphism involves the stage of crystal nuclei formation. During the nucleation stage, some molecules can leave the preformed aggregates, leading to their complete dissolution. The surviving aggregates provide the new differently arranged templates for the subsequent growth stage, and the molecular arrangement in largest amount will form the nuclei that will grow in a particular crystal form. The critical dimension that the aggregates must reach to survive depends of the supersaturation level; therefore, the entire process is under kinetic control rather than thermodynamic (Volmer 1939; Ostwald 1987). Today, the interest for the phenomenon of polymorphism is increasing, particularly for pharmaceutical industry where its study is became integral part of the drug optimization process (Brittain 1999). Paracetamol (Beyer et al. 2001), famotidine (Lu et al. 2007), and piroxicam (Giordano et al. 1998) are the classical examples of drugs crystallized in several forms, each having different chemical and pharmaceutical proprieties. Usually, pharmaceutical industry prefers the most stable form with respect to that metastable, although, at the same concentration, the latter is more available in the organism due to its higher solubility. Also protein molecules can crystallize in several crystal forms, as a consequence of the different conformations assumed by peptide chain in a given condition. A classic example of polymorphism for crystal of proteins is the lysozyme that crystallizes in six different crystalline forms. Another important example is the ubiquitin, whose crystal form depends on the nature and the amount of the metal ion used during the crystallization (Arnesano et al. 2011; Falini et al. 2009). The technology of membrane crystallizers gives the opportunity to drive the crystallization toward a specific polymorph. This is possible by regulating the degree and the rate to which of supersaturation is reached through the

managing of the transmembrane flux and an accurate choose of the membrane properties (Di Profio et al. 2007, 2009, 2013). So crystallization assisted by membrane can occur both under thermodynamic and kinetic control: low evaporation rates through the membrane allow the growth of the more stable nuclei at the expense of the less stable forms (thermodynamic control), while the induction of a more rapid nucleation increases in the presence of higher evaporation rates and increases the conversion rate from the stable to the metastable form (kinetic control). The relative amount of the two forms depends on the ratio between the conversion and crystallization rate. Similarly, the production of a specific polymorph can be obtained by using antisolvent membrane crystallization processes (Di Profio et al. 2010).

Crystal Purity

Benny Danilo Belviso

Istituto di Cristallografia, Consiglio Nazionale delle Ricerche (C.N.R.), Bari, Italy

Crystal purity is the parameter used to indicate the contamination level of a crystal and represents one of the most important properties of the crystalline materials. Crystal purity is also an index of the heterogeneity of the substance to crystallize, in particular in the presence of proteins or nucleic acids, whose uncontrolled modifications may increase the number of species in the crystallizing solution. Contaminants may distort the crystal lattice, affect the crystal features, such as diffraction quality, and change the crystal morphology in particular when the impurities are incorporated in the crystal at different rates into adjacent steps on the crystal surface. However, the main feature of a low-purity crystal is its higher internal energy with respect to that in absence of impurities (van Enkevort and van der Berg 1998; Davis et al. 2004), which causes an increase of the crystal solubility and a decrease of the effective supersaturation level of the solution containing the substance to crystallize: the higher the contamination, the more difficult the crystallization because the dissolution probability of the crystals increases. Given this, many efforts should be devoted to adequately purify the substance to crystallize, by paying attention to the purity grade of the chemicals employed in each step. Particular attention should be paid for precipitant agents, since they are used in very high concentrations: accordingly, salts and polymeric precipitants, such as polyethylene glycol or alcohols, should be recrystallized or purified, respectively. Once the crystal is formed, washing procedures

may be carried out to increase crystal purity by removing many of the surface impurities or those specifically attached inside the crystal. However, the technique is quite risky, since the washing solvent should be able to remove the impurities without dissolving the crystal. Although contamination is usually the first cause of unsuccessful crystallization, the alone presence of impurities is not sufficient to frustrate the crystallization attempts. Crystal features, such as crystal lattices having weak interactions between atoms or containing large empty spaces where foreign molecules have possibility to fit, should be avoided to reduce the probability of crystal contamination. Impurities are included in a crystal as a result of the processes that occur concomitantly to the crystallization (in particular during the nucleation) or after that crystal growth has finished. Particularly, the degree of crystal purity depends on the ratio between the rates of these inclusion processes with that of the crystallization process that, being a purification process, pushes toward the recovery of the desired product without contaminations (Burton et al. 1953): usually, slow crystallizations allow the substance to crystallize to properly fit in the lattice, differently from more rapid precipitations, where the insertion of the impurities results facilitate. In addition, high supersaturation often leads to contaminant inclusions that reduce the crystal purity. At the present, membrane technology represents one of more promising tools to produce high-purity crystal. By controlling the transmembrane flux, membrane crystallizer can limit the maximum level of supersaturation and reduce the growth rate to reach the critical threshold, beyond which inclusion of impurities occurs (Weckesser and König 2008; Mullin 1993). Today, the advances made in the development of membrane-assisted crystallization allow producing crystalline materials having the purities required for their commercialization as purified product. One of the most important examples is represented by the production of sodium carbonate crystals having purity grade that reaches ca. 99.5 % also starting from crystallizing solutions containing concentrations ranging from 0.2 to 0.6 M of impurities, such as sodium nitrate, sodium sulfate, and sodium chloride

(Ye et al. 2013). In addition, membrane devices are also used to produce high-purity cocrystal, a challenge particularly interesting for pharmaceutical industry.

(in g/cm²), and C_f is the sensitivity factor for the crystal used (in Hz.cm².ng⁻¹). This sensitivity is proportional to the square of the resonant frequency, according to the expression

$$C_f = \frac{\Delta f}{\Delta m} = -\frac{2}{\rho v} \frac{f_n^2}{n}$$

where ρ is the quartz density, v is the propagation velocity of the wave in the crystal, f_n is the frequency of the selected harmonic resonant mode, and n is the harmonic number ($n = 1$ for the fundamental mode). By way of comparison, the typical balances used in research labs (torsion, cantilever, or spring balances) are able to detect mass until 10⁻⁷ g, while QCM can detect up to 10⁻¹³ kg (Mecea 2005). For many years QCMs were only applied as gas-phase mass detectors in physical vapor deposition systems. Their application has been extended recently, with other uses beyond mass deposition, including the monitoring of adsorption kinetics for biomolecules and sensors based on QCM detection.

Crystal Quartz Microbalance

Oswaldo N. Oliveira Jr. and Diogo Volpati
Sao Carlos Institute of Physics – IFSC, University of Sao Paulo – USP, Sao Paulo, Brazil

The quartz crystal microbalance (QCM) is a mass sensor able to measure mass below the nanogram scale range. This device was first introduced by Sauerbrey in 1959 (Sauerbrey 1959), and its operation is based on a piezoelectric plate of quartz with two electrodes fixed to the plate. The small mass absorbed at the crystal is detected by decreasing the resonant frequency of the crystal. The Sauerbrey's equation is used to associate the mass adsorbed at the QCM crystal surface with the change in oscillation frequency of the crystal:

$$\Delta f = -C_f \Delta m$$

where Δf is the experimental frequency shift (in Hz), Δm is the change in mass per unit area

Crystal Quartz Microbalance for Protein Adsorption Measurement

Oswaldo N. Oliveira Jr. and Diogo Volpati
Sao Carlos Institute of Physics – IFSC, University of Sao Paulo – USP, Sao Paulo, Brazil

With the advent of biosensors, techniques able to monitor the immobilization of active molecules on electrodes become essential, especially those able to provide molecular-level information for the adsorption process. Proteins represent an

example of molecules largely used in biosensors, and their immobilization process onto electrode surfaces has been monitored by techniques such as fluorescence labeling (Lee 1997), microarray techniques (Park et al. 2008), surface plasmon resonance (SPR) (Smith et al. 2003), and quartz crystal microbalance (QCM) (Cooper and Singleton 2007). The latter has become the most used because it allows for determining the amount of bound molecules at the electrode surface and evaluation of the adsorption kinetics and of the affinity between ligands and analytes in sensors.

A quartz crystal microbalance (QCM) is a device often used to monitor the material adsorption, being capable to detect mass change of the order of 10^{-9} g in commercial systems. The QCM principle of operation is based on changing the resonance frequency of a quartz crystal by adsorbing mass on its surface (Montagut et al. 2011). For monitoring protein adsorption, usually a ligand is immobilized as a monolayer on a gold surface. Since gold reacts with thiols producing active sites at the surface, proteins can be immobilized by the thiol groups from their cysteine residues or can be activated by using a thiol-containing bifunctional linker (Bieri and Burgi 2006).

Crystal Seeding

Benny Danilo Belviso

Istituto di Cristallografia, Consiglio Nazionale delle Ricerche (C.N.R), Bari, Italy

Synonyms

Seeding

Crystal seeding is a technique widely employed to provide preformed templates (seeds) on which new molecules can converge to form crystals. Crystal seeding is said homogeneous if the seeds are made of the same molecule to crystallize, as occurs in macroseeding, microseeding, and streak seeding, and heterogeneous if it foresees the use of foreign material, such as porous silicon and mica (Saridakis and Chayen 2009), as in the case of cross seeding and epitaxial growth. Whatever the kind of used seeds, their presence generally makes less energetically expensive the entire crystallization process, because it allows the passing directly to the crystal growth stage without dealing with the intrinsic uncertainties of the nucleation. However, the usage of seeds might have the disadvantage to affect the crystal growth and the forming crystal lattice (Hermes et al. 2011; Liu et al. 2007). The first step for much of seeding techniques is the production of seeds: during this phase, preformed crystals are washed to remove defects and impurities that could block the crystal growth, stabilized in an appropriate solution, and crushed by using a glass homogenizer or by using spherical beads. Once the seed stock has been obtained, pre-equilibrium conditions (e.g., temperature, precipitant agents, additives, etc.) of the solution to seed are carefully determined together with the appropriate level of supersaturation, in order to avoid the trigger of a self-nucleation that would frustrate all following efforts. In the absence of such information, the seeding process could result in a dissolving of the seeds or in a rain of tiny and poor-quality crystals. In order to assess seeding conditions, protein crystallographers usually exploit streak seeding

technique, where a synthetic or natural fiber (Bergfors 2003) is used to crush existing crystals and to introduce the resulting small crystalline particles into different pre-equilibrated solutions: mode and timing of seed growth allow to determine both the appropriate range of pre-equilibration conditions and the dilution of the seed stock. Although the techniques of seeding were initially developed with the aim to optimize and make more reproducible the crystallization processes performed in laboratory, today they are widely employed also in high-throughput processes that range from the industrial crystallizations to the preparation of devices employed in membrane reactors or in separation processes, such as membranes of zeolite (Li et al. 2005) or silicate crystals (Hasegawa et al. 2006). Preparation of these membrane devices is very challenging because it requires a strong control of the seeding in order to obtain high-quality membranes having determined features, such as a specific crystalline orientation (Caro et al. 2000). Several seeding techniques have been developed to produce a membrane of zeolite crystal (Table 1), and the secondary growth together with dip coating is considered among those most promising: secondary growth exploits a hydrothermal treatment of the membrane support that has been previously covered with layers of seeds (Lovallo and Tsapatsis 1996), while dip coating takes advantage from the capillary force to aid the deposition of crystal seeds (Lovallo et al. 1998; Bernal et al. 2001). In addition, filtration

procedures, such as cross-flow filtration and dead-end filtration (Pera-Titus et al. 2005; Huang et al. 2004), based on the seed deposition on the membrane support under the action of a difference of pressure applied, have been also developed.

Crystallization

Benny Danilo Belviso

Istituto di Cristallografia, Consiglio Nazionale delle Ricerche (C.N.R.), Bari, Italy

Crystallization is a phase transition that takes place from the liquid toward the solid state resulting in the formation of crystals; less frequently, the deposition of crystals can also occur starting from the gas state. In any case, crystallization process represents a particular kind of solidification in which the molecules or ions of a given substance arrange themselves in an orderly fashion according to a substance-specific

three-dimensional lattice. Differently, in the absence of orderly arrangement, solidification process leads to amorphous precipitates or to solids consisting of a mix of crystalline and amorphous areas (as it happens for some polymers). Crystallization takes place when the solution containing the substance to crystallize reaches the supersaturation state, namely, when the concentration of this substance overcomes the solubility limit while remaining below the threshold of precipitation. The kinetics and the thermodynamics of the crystallization depend on the supersaturation level that, hence, represents the driving force of the entire process. Crystallization consists of two major events: nucleation and crystal growth. Nucleation occurs in the metastable zone (Fig. 1, in yellow) as a consequence of the rapid local molecular collisions characterizing the homogeneous phase (solution or gas) in condition of supersaturation. Crystalline nuclei, the smallest molecular aggregates having a structure ordered according to periodic rules, can be formed only when well-oriented collisions between particles take place. The smallest nuclei dissolve, while crystal nuclei having critical dimensions pass to the next step, where other molecules of solute can converge on the preformed aggregates. This stage is called crystal growth and takes place in the

Crystallization,

Fig. 1 Crystallization phase diagram. Crystal nucleation takes place in metastable zone (in yellow) and crystals growth in labile zone (in pink), both belonging to the supersaturation zone. The condition of supersaturation is reached when solute concentration is slightly higher than the solubility (gray line); differently, a much higher solute concentration leads to amorphous precipitation (light cyan area)

labile zone (Fig. 1, in pink). During the crystal accretion, also the concentration of contaminants on crystal surface increases causing a slowdown of the growth up to its complete stop. The adding of small particles, such as small crystals or amorphous solids (Saridakis and Chayen 2009), can promote the crystallization process by acting as nucleation centers. Although the rates of nucleation and crystal growth increase with the supersaturation level, fast crystallization processes at low supersaturation are possible in the presence of crystal defects. Today, advanced crystallization techniques allow getting crystals with few defects even starting from lower levels of supersaturation. This is possible by means of an effective control of the nucleation and crystal growth steps, as occurs in the case of the membrane-assisted crystallization (Drioli et al. 2012), where the entire crystallization process takes place on a support consisting of a polymeric membrane that acts also as active surface for heterogeneous nucleation (Di Profio et al. 2010a). On the other side of the membrane (distillate side), a stripping solution allows the removal of the solvent from the crystallizing solution. The high hydrophobicity of the membrane prevents its wetting, allowing that the mass transfer between crystallizing solution and stripping solution takes place only by vapor diffusion mechanism. Since the solute species, such as macromolecules and electrolytes, have lower volatility than the solvent, only the latter passes from the crystallizing solution to the stripping solution through the membrane, by resulting in an increase of solute concentration. Therefore, the driving force of the membrane-assisted crystallization is represented by the vapor pressure gradient at both sides of the membrane. Kinetics and thermodynamics of the nucleation process can be modulated according to the transmembrane flux and the features of the membrane, offering the opportunity of a more rationale design of the crystallization process. Crystallization on membrane has been extensively tested both on small molecules (Di Profio et al. 2010b, 2013) and on large macromolecules, such as proteins (Di Profio et al. 2005; Curcio et al. 2005).

Crystallizing Solution

Benny Danilo Belviso

Istituto di Cristallografia, Consiglio Nazionale delle Ricerche (C.N.R.), Bari, Italy

Crystallizing solution (also called crystallizing cocktail) is the ensemble of chemicals able to promote the crystallization of a substance in a given physical condition (e.g., temperature, vibrations, surface of crystallization, etc.). Crystallization requires that the solution containing the substance to crystallize is supersaturated with respect to the latter, namely, that the solute concentration is higher than its solubility limit but lower than the precipitation threshold: an appropriately formulated crystallizing solution reduces the solubility of the substance (both in the case of small inorganic/organic molecules and biological macromolecules, such as proteins), enabling a

Crystallizing Solution, Fig. 1 Vapor phase transfer in membrane crystallizers. (a) On the crystallizing solution side, the solute concentration increases due to the solvent removal triggered by the gradient of vapor pressure between the two sides of the membrane. (b) In the case of

antisolvent membrane crystallizers, the solubility of the solute decreases due to the increase of the antisolvent concentration inside the crystallizing solution usually generated by a temperature difference between the two sides of the membranes

more easily reaching of the crystallization range, where spontaneous formation of the first crystalline nuclei and their next growth can occur. Usually, crystallizing solution consists of a precipitating agent, a substance whose concentration is inversely correlated to the solubility of the molecule to crystallize, and a buffer salt able to stabilize the pH during the crystallization process. In order to optimize the crystallization, additives, whose concentration is lower than that of the main components, can be added. In the case of crystallization of proteins, ligands and cofactors can be exploited to stabilize the protein or to increase its conformational purity. Notwithstanding it is common to classify the components of a crystallizing solution according to these three categories, a sharp distinction is not possible because a substance might act as precipitating agent in a given cocktail and be used as an additive in a different case. Besides to affect the solubility, the components forming the crystallizing solution have to weakly interact with the molecule of the substance to crystallize (Wilson 2003). Differently, stronger interactions make more soluble the substance to crystallize, while the absence of interactions drastically reduces the solubility, resulting in an amorphous precipitation. As the space of the conditions (nature and concentration of each component)

promoting weak interactions is usually very small, it is necessary to explore several formulations before obtaining the best one. One of the most used methods to deal with the crystallizing solution formulation problem is the multivariate analysis that allows testing several successful events of crystallization against a high-dimensional space represented by the crystallization conditions (Segelke 2001). Depending on the crystallization method, the concentration of each component of the crystallizing solution can vary or keep unchanged during the crystallization process: no change occurs in the case of the batch method where the level of supersaturation is directly adjusted on the crystallizing solution. Conversely, the component concentrations change when the supersaturation level is reached in the time by using vapor or liquid diffusion techniques. Techniques that exploit membranes to put in contact a crystallizing solution containing the molecule to crystallize and a stripping hypertonic solution or an antisolvent on the other side of the membrane (distillate side) belong to the latter category. Due to its hydrophobicity, membrane is not wet by the two liquids on the two sides and the flux of solvent molecules through the membrane can occur by vapor diffusion (Fig. 1a). Accordingly, it is possible to achieve a

fine regulation to the rate to which solute increases its concentration in the crystallizing solution by managing the transmembrane flux. Similarly, in the case of antisolvent membrane devices, vapor diffusion triggers the increase of the antisolvent concentration inside the crystallizing solution (Fig. 1b), resulting in a decrease of the solute solubility (Di Profio et al. 2009). By using hydrophilic membranes, it is possible to exploit liquid-phase transfer: in this case, crystallizing solution is directly pressed through a porous membrane in an antisolvent (or vice versa). This technique has been used to produce crystal of L-asparagine with narrow size distribution (Zarkadas and Sirkar 2006).

Cutoff Membrane

Xianhui Li and Jianxin Li
State Key Laboratory of Separation Membranes and Membrane Processes, School of Materials Science and Engineering, Tianjin Polytechnic University, Tianjin, China

The membrane filtration is a very efficient and economical way for separating components that

are suspended in a liquid or mixed in the gas. The membrane is a physical barrier that allows certain compounds to pass through, depending on their physical and/or chemical properties. Therefore, the cutoff property of membrane is a significant parameter.

In the liquid separation process, a membrane filter comprises a membrane with a pore size between 5 nm and 50 μm . On the basis of the cutoff membrane rate, the membrane technologies can be classified into microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO) (Table 1). The MF membrane has pore sizes in the range of 0.1–5 μm and is capable of removing suspended particles like blood cell, microorganism, and latex emulsions. The UF membranes with pore sizes in the range of 2–100 nm can remove large molecules like albumin, bacteria, or pepsin. The cutoff membrane rate of UF can also be characterized in terms of the so-called molecular weight cutoff (MWCO), which is generally expressed in standard dalton (Da) or kilodalton (kDa) units. While this classification method is inherently deficient since the atomic mass does nothing to describe the actual size or geometry of a molecule, it remains the standard convention for UF membrane classification. NF membrane has a pore size less than 1 nm. It can separate small molecules like divalent salts, dissociated acids, and sugar. NF membranes are generally characterized by their ability to retain a divalent ionic species such as magnesium sulfate (MgSO_4) or calcium chloride (CaCl_2). The typical rejection rate of MgSO_4 might range from around 80 % to 98 %. RO membrane with pore sizes in the range of few angstroms can separate water molecules or ions like sodium and chloride on the molecular or ion level. The typical rejection rate of RO for NaCl can be on the range of 98–99.5 %, which is influenced by given pressure, temperature, and concentration conditions. However, the gas separation requires membrane with small pore size.

Many characterization methods like permoporometry, thermoporometry, mercury porometry, gas adsorption–desorption, nuclear magnetic resonance (NMR), and liquid–liquid porometry, along with several microscopic

Cutoff Membrane, Table 1 Cutoffs of different liquid filtration techniques

Micrometer	0.001	0.01	0.1	1	10	100	1000

techniques, have been used to characterize the membrane pore and pore size distribution. Each of these methods has different characteristics and relies on different theoretical considerations to be taken into account to convert the direct results into pore sizes. Among these techniques, the bubble point test has gained enormous relevance for the characterization of MF membranes. However, it cannot be properly applied to UF membranes due to the high pressure (more than 10 bar) necessary to evaluate pore with sizes below 0.1 μm . On the contrary, the liquid–liquid displacement porometry (LLDP) is very suitable for characterizing UF membranes at relatively low applied pressures. However, for the dense nonporous membrane such as NF, RO, and gas separation membranes, some experimental techniques such as positron annihilation lifetime spectroscopy, inverse gas chromatography, and Xe NMR are available for determining the average radius (1–10 Å) and the size distribution of the free-volume elements. And atomistic modeling can only explain the topology and structure of free-volume elements in polymers.

Generally, the selection of a membrane cutoff rating is 0.2–0.3 times the value of the molecular weight targeted for retention. Thus, prior to use, it is necessary to characterize physical

characteristics such as pore size distribution (and mean pore size), porosity (void volume), and tortuosity (or the relative length of the path of diffusion across the membrane material).

Cyclodextrin in Membranes

Francesco Trotta

Department of Chemistry, University of Torino, Torino, Italy

Cyclodextrins have the unsurpassed ability to form inclusion compounds with suitable guest molecules. Interaction of native and modified cyclodextrins with cellular membrane was intensively studied in view of their large use as drug delivery systems. Moreover, cyclodextrins have found many potential applications in membrane science. In this latter case, in addition to the ability to form inclusion complexes, also the intrinsic chirality of the cyclodextrins and their enzyme-like behavior were exploited in membrane applications. Almost all the membrane processes are involved independently from their driving forces applied (Kozłowski and Sliwa 2008). Native

cyclodextrins, but also dimers, modified cyclodextrins, polymers, and specially cross-linked cyclodextrins were used. Cyclodextrin can be grafted to polymer chains, dispersed in casting solutions to form composite membranes, used as carriers in liquid membranes, bonded to ceramic membranes, or cross-linked alone or with suitable organic polymers. In this latter case, formaldehyde, glutaraldehyde, citric acid, hexamethylene diisocyanate, tetramethyl orthosilicate, as well as ethylene glycol diglycidyl ether were used as cross-linking agents. The main organic polymers used were PVDF, polyvinyl alcohol, polydimethylsiloxane, silicone rubber, polypyrrole, polyurethane, poly(*N*-isopropylacrylamide), polyamide-imide, polysulfone, PVC, polyacrylonitrile, PEEK-WC, as well as chitosan, cellulose, and cellulose diacetate. Flat sheet and hollow fiber membrane configurations were reported. Phase inversion technique and casting followed by a cross-linking reaction were the most used procedures to get cyclodextrin-containing membrane; however, other techniques were also employed, i.e., electrospinning. As carriers in liquid membranes, cyclodextrins allow the selective transportation of saccharides and to achieve good results in this difficult separation. Organic structural and geometrical isomer enrichments were obtained by using water-based liquid membranes. Liquid-liquid extraction was also used to separate racemic mixtures because the cyclodextrin nanocavity allowed the formation of diastereomeric complexes. Enantiomeric discrimination of native aromatic amino acids was also performed. Chiral enrichment of racemic chlorthalidone and propranolol was achieved using bulk liquid membrane containing cyclodextrin as a mobile enantioselective carrier. Because of their different ability to complex isomers, immobilized cyclodextrins also largely influenced permeation in dialysis membranes. In this way, *ortho*, *para*, and *meta* isomers of aromatic compounds were successfully achieved as well as the enantiomeric separation of aromatic amino acids. Pervaporation processes were also greatly influenced by the addition of cyclodextrins or cyclodextrin derivatives prevalently in PVA membranes. Thus,

propanol isomers, xylene isomers, and water/ethanol and water/1-propanol or 2-propanol were studied at length as were permeabilities greatly influenced by cyclodextrin contents. Pervaporation membranes were also produced by using polyurethanes polymers hosting cyclodextrins. This system was used essentially to separate phenol/water mixtures. Polyimide-based cyclodextrin-containing membranes found application in isopropanol dehydration and butanol isomer separation. Cyclodextrin was used in membrane reactors as an additive to obtain enantiomeric separation, being the reaction catalyzed by enzyme or exploiting the enzyme-like behavior of water-insoluble modified cyclodextrin dispersed in PEEK-WC membranes.

Polyimide polymer membranes added to cyclodextrins alone or grafted onto carbon nanotube surfaces have a relevant influence on CO₂/CH₄ as well as propane/propylene gas separation. The characteristics of cyclodextrins fit well with the requirements for membrane sensor-making. Depending on the cyclodextrins and membranes used, excellent selectivity toward glucose, tetracycline, several heavy metal cations, and even an enantioselective determination of R-clenbuterol was reported. In this latter case, a detection limit of 2.99×10^{-7} mol/L was reached. The introduction of cyclodextrins into the polysulfone membrane structure greatly influenced the rejection of humic acid and natural organic matter from water. Again polysulfone/CD membrane found uses in endocrine disruptors removal from water. Alternatively, acid dyes can be removed from wastewater by using a chitosan membrane modified with cyclodextrin. Ceramic membranes impregnated with cyclodextrin polymers are effective in facilitating polycyclic aromatic hydrocarbons' removal. In addition, the polyacrylonitrile membrane with triacetyl- β -cyclodextrin is able to reduce the amount of pesticides in citrus essential oil. Both hydrophobic β -cyclodextrin polymers in triacetate membrane and polypyrrole polymer membrane doped with sulfated α -cyclodextrin facilitate the transport of heavy metal cations from aqueous solutions. The high versatility of membrane processes allows the preparation of

composite Nafion membranes with sulfated- β -cyclodextrin. This induces a remarkable increase on proton conductivity with a very slight increase in methanol permeability. Even better results were achieved by using sulfonated PEEK membranes. Anion exchange membrane performances in electrodialysis processes are influenced by the introduction of cyclodextrins in the polymer network. Due to the changes in the hydrophilicity of the environment, transport of less hydrated anions decreased, while transport of strongly hydrated anions increased by enhancing the content of cyclodextrin. Minor application of cyclodextrins was also found in UF, NF, RO, temperature-controlled membrane processes, and a new drug delivery system.

Cyclodextrins

Francesco Trotta

Department of Chemistry, University of Torino,
Torino, Italy

Cyclodextrins (Astray et al. 2009; Loftsson and Duchene 2007; Martin Del Valle 2004; Szejtli 1998; Szente and Szeman 2013) (Schardinger dextrins, cycloamylose, cyclomaltose) (Fig. 1) are cyclic nonreducing oligosaccharides obtained through the enzymatic degradation (*cyclomaltodextrin glucanotransferase*) of starch. They are made up of six, seven, or eight glucose units linked by 1–4 α glucoside bonds and have a typical truncated cone-like shape. They are named α -, β -, and γ -cyclodextrin, respectively. Larger cyclodextrins, i.e., δ and ϵ , are also known, but they are much more expensive, have a twisted structure, are less stable, and are of limited interest. The position of the atoms form a

lipophilic cavity surrounded by a hydrophilic rim being the OH groups located on the exterior edge. Primary hydroxyl groups are all located on the narrow edge of the truncated cone being the secondary positioned on the larger edge. The reactivity of the hydroxyl groups differs enough to be used in selective modification of the native cyclodextrins. Cyclodextrins were first discovered by French chemist A. Villiers in 1891 as a by-product in the production of dextrins. A few years later, Austrian chemist F. Schardinger isolated the strain on bacteria (*Bacillus macerans*) responsible for the synthesis of cyclodextrins. However, it was only through the work of Freudenberg in 1935 that the cyclic nature of cyclodextrin was discovered. The toroidal structure of cyclodextrins allows them to form inclusion compounds with a great set of molecules with suitable polarity and size. The polarity of the inner nanocavity is believed to be similar to an aqueous ethanolic solution. The inner cavities have a diameter in the range of 0.47–0.53, 0.60–0.65, and 0.75–0.88 nm, respectively. On the other hand, the height (0.79 nm) is the same for all three native types. Generally speaking, the internal diameter of the cavity mostly accounts for the encapsulation of the guest molecule. The smaller α -cyclodextrin complex compounds with linear aliphatic chains, β -cyclodextrin includes well aromatic structures, and γ -cyclodextrin accommodates larger molecules. All native cyclodextrins are quite safe and can be orally administered without toxic effects because they are not absorbed by the gastrointestinal tract. On the other hand, both parent α - and β -cyclodextrins are not suitable for parenteral administration. α - and γ -cyclodextrins have good water solubility, but β -cyclodextrins have limited solubility in water, i.e., 1.85 wt.% at room temperature. In any case, the water solubility of the parent cyclodextrins is much lower than corresponding linear oligosaccharides. Solubility increases to a large extent by increasing the temperature and/or pH. Inclusion compounds can be produced following several techniques such as grinding, freeze-drying, spray-drying, kneading, coprecipitation, melting, evaporation, etc. Hydrophobic molecules are incorporated into the cavity of cyclodextrins by displacing

Cyclodextrins, Fig. 1 Molecular structure of native cyclodextrins

water. This effectively encapsulates the molecule of interest within the cyclodextrin, rendering the molecule water soluble. When the water-soluble complex is diluted in a much larger volume of aqueous solvent, the process is reversed, thereby releasing the molecule of interest into the solution. The encapsulation of the guest molecules inside the cyclodextrin cavity leads to many changes in their physical-chemical properties. In particular, cyclodextrins can:

1. Increase the solubility of poor water-soluble molecules and drugs
2. Transform liquid in solid powder
3. Host volatile molecules in solid form
4. Mask smell and taste
5. Protect substances by light and oxidation
6. Act as enzyme-like catalysts
7. Act as inverse phase catalysts
8. Change membrane permeabilities

The abovementioned properties allow cyclodextrin to find many applications in cosmetics, separation, laundry, catalysis, drug delivery, analytical chemistry, food additive, agriculture, and chemical industries. Although several hundred cyclodextrin derivatives were already

reported in the literature, only few have found industrial application due to their superior performances and safe profile: hydroxypropyl β -cyclodextrin and sulfobutyl ether β -cyclodextrin. Random methylated β -cyclodextrin is also of interest but it cannot be used in drug delivery due to its toxic effects. In order to increase the stability constant of the inclusion complexes, dimer and trimer of cyclodextrin were synthesized as well as linear and cross-linked polymers. The latter can act as nanosponges, nanocontainers, or nanocarriers.

Dead-End Filtration

Xianhui Li and Jianxin Li

State Key Laboratory of Separation Membranes and Membrane Processes, School of Materials Science and Engineering, Tianjin Polytechnic University, Tianjin, China

The dead-end filtration is the one where the flow of water is perpendicular to the membrane surface (Fig. 1a). And the water is pushed through the membrane by pressure. All the water that is introduced in the dead-end cell passes through the membrane. In other words, there is no retentate. In dead-end filtration the retained particles build up with time on the membrane surface or within the membrane. In either case, the building particle would result in the increase of layer thickness and cause the permeate flux to decline (Fig. 1b). Thus, the dead-end filtration requires the stopping of filtration to clean or replace the membrane. Therefore, this type of filtration is also called batch filtration.

There are two types of filtration which can be employed in a dead-end filtration unit: constant flux and constant pressure. The dead-end filtration

with constant flux ensures that the permeate flux through the membrane remains constant. This filtration can be achieved by positive displacement pump. As the cake buildup increases with time, the pressure drop would increase so as to maintain constant flux. The constant flux strategy is usually applied in the industrial applications. Since the produced volume is a main operating goal. In another dead-end filtration mode of constant pressure, the permeate flux decreases as the cake build-up with the time. The constant pressure strategy is commonly chosen in the laboratory scale installations, because this is easy to implement on a small scale.

However, the dead-end filtration performance is often limited by fouling phenomenon owing to its filtration characteristics. Some strategies are employed to control membrane fouling, such as module design, pretreatment, or hydrophilic modification of membrane materials. Four distinct models based on Darcy equation can be used to describe the dead-end fouling behavior (Table 1). The relationships described were the complete blocking model, which assumes that each particle that deposits on the membrane will seal a membrane pore; the intermediate blocking model, which assumes that only a portion of the deposited particles will seal a membrane pore; the standard

Dead-End Filtration, Fig. 1 Schematic diagram of dead-end filtration (a) and representation of flux rates and layer thickness (b)

blocking model, which assumes that the pore volume will decrease proportionally to the filtrate volume by deposition of solids on the pore walls; and the cake filtration model, which assumes that the cake resistance is proportional to the filtrate volume by deposition of solids on the membrane surface.

The mathematical expressions for these laws are summarized in Table 1. For a constant pressure filtration mode, they have been reformulated in a common frame of power-law relationships (Hermia 1982):

$$\frac{d^2t}{dV^2} = k \left(\frac{dt}{dV} \right)^n \quad (1)$$

Table 1 also presents the physical basis for each fouling mechanism and the corresponding n -value. Each of these mechanisms could be alone or in combinations, to explain experimental observations. Overall, the membrane fouling control is a key problem for the large-scale application.

Dead-End Filtration, Table 1 Fouling mechanisms and their corresponding physical basis (Grenier et al. 2008)

Fouling mechanism	n	Corresponding linear form	Physical concept	
Cake filtration	0	$\frac{dt}{dV} = \frac{1}{Q} = f(V)$	Surface deposit	
Intermediate blocking	1	$\frac{dt}{dV} = \frac{1}{Q} = f(t)$	Pore blocking and surface deposit	
Standard blocking	1.5	$\left(\frac{dV}{dt} \right)^{1/2} = Q^{1/2} = f(V)$	Pore constriction	
Complete blocking	2	$\frac{dV}{dt} = Q = f(V)$	Pore blocking

Dealcoholization by Pervaporation

Shota Ando, Shuichi Sato and Kazukiyo Nagai
Department of Applied Chemistry, Meiji
University, Tama-ku, Kawasaki, Japan

Dealcoholization by pervaporation (PV) is one of the most innovative processes for the selective separation and condensation of ethanol from a dilute aqueous solution of ethanol obtained from biomass fermentation (about 10 wt%) using PV method. The energy for bioethanol that is produced using distillation requires approximately 1.5 times than that obtained from ethanol fuel. Among them, about 70 % is estimated to be

consumed in distillation. Thus, dealcoholization by PV is efficient because of energy conservation and separation of an azeotropic mixture, which cannot be separated by distillation. In PV, a liquid mixture is supplied to a membrane on one side. The permeated components are evaporated from the other side (Fig. 1). Thus, the driving force of this process is a gradient of partial pressure or chemical potential located across a membrane. To enhance the flux or the total amount of the product, the permeated side is always maintained at a pressure below the saturated pressure of a given component, either under a vacuum or by sweeping the vapor using a carrier gas. The vapor at the permeated side is then condensed and recovered as liquid (Nagai 2010). The features of this method are: (1) increased separation performance from solution, diffusion, and vaporization; (2) the driving force of permeation does not depend on the pressure and is applicable to the organic liquid solution with high osmotic pressure; (3) PV does not need pressurization; (4) this method can be applied to separate the mixture solution, which cannot be done by distillation, for example, the separation of the thermal denaturation/thermally decomposable mixture, azeotropic mixture, near-

Dealcoholization by Pervaporation,
Fig. 1 Dealcoholization by a pervaporation process

boiling point mixture, and structural/optical isomers can be concentrated; (5) the reaction can be promoted because of the movement of the equilibrium reaction; and (6) the method does not pressurize, and no consolidation of the membrane occurs. The term PV is a compound word of Permeation and Evaporation. Moreover, it has been originated from the article of Kober (1917). There are two kinds of method for alcohol concentration by PV. The alcohol-selective method removes alcohol from the dilute alcohol aqueous solution of concentrated alcohol, whereas the water-selective method removes water at a high-concentrated alcohol solution. The materials differ according to their use. The alcohol-selective method uses silicone gum and poly(1-trimethylsilyl-1-propyne). By contrast, the water-selective method uses cellulose acetate and poly(phenylene oxide), which yield good results. Generally, the alcohol-selective method is called dealcoholization by PV. Researches on alcohol-selective permeable membranes are fewer than those on water-selective permeable membranes. In addition, membranes with performance that can be set in bench-scale plants have not been developed. Thus, the developments of alcohol-selective permeable membranes are delayed compared with that of water-selective membranes. The cause is due to the larger molecular size of alcohol molecules, which are permeated preferentially, compared with that of water molecules. When alcohol from alcohol aqueous solution is permeated preferentially, separation on the diffusion process cannot be expected in PV method based on a solution-diffusion mechanism. Thus, separation can be performed using the difference in the only solution process of both components of the membrane. However, the membrane is excessively swelled by very high affinity to alcohol because it is in direct contact with the mixture solution to be separated in PV method. Thus, permeability increases. However, the small molecular size of water enters the membrane by the plasticizing effect because of membrane swelling, which significantly reduces the selectivity to alcohol. To solve this problem, the balance of hydrophobicity and affinity of the membrane is examined by graft, copolymers, multiblock,

blend, and three dimensional structures by cross-link. In each case, there is a limit to improvement in separation performance by previous method because there is a discrepancy between affinity and swelling.

Dearomatization by Membrane Operations

- [Aromatic and Nonaromatic Separation by Membrane Operations](#)

Decatungstate, Catalytic Membrane Containing

Enrica Fontananova
 Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Catalytic membrane containing decatungstate is a polymeric catalytic membrane applied on a lab scale in liquid phase photooxidation reactions (Drioli and Fontananova 2010).

The decatungstate ($W_{10}O_{32}^{4-}$) is a photocatalytic polyoxometalate (polyanionic metal oxide cluster of early transition metals) with remarkable properties for application in oxidation catalysis for fine chemistry and wastewater treatments.

In particular, decatungstate exhibits interesting properties for the photocatalytic detoxification of wastewater since its absorption spectrum ($\lambda_{\max} = 324 \text{ nm}$) partially overlaps the UV solar emission spectrum, opening the potential route for an

Decatungstate, Catalytic Membrane Containing,**Fig. 1** Chemical formula of the polymers used to prepare the catalytic membranes entrapping decatungstate

environmentally benign solar-photoassisted application (Texier et al. 1999).

However, decatungstate has also some relevant limitations: low quantum yield, small surface area, poor selectivity, and limited stability at pH higher than 2.5 (Mylonas et al. 1996).

Membrane technology can offer the possibility to overcome these limitations by the multi-turnover recycling associated to heterogeneous supports, the selectivity tuning as a function of the substrate affinity toward the membrane phase, and the effect of the polymeric microenvironment on catalyst stability and activity.

In this respect, the design of alternative heterogeneous photooxygenation systems able to employ visible light, oxygen, mild temperatures, and solvent with a low environmental impact (water or neat reaction) was investigated by the immobilization of the decatungstate in polymeric membranes (Bonchio et al. 2003; Carraro et al. 2006; Fontananova et al. 2006; Drioli et al. 2008).

The successful heterogenization was guaranteed by a proper choice of both the catalyst functionalization and the polymer material.

Considering the interest toward the photooxidation reactions of organic substrates, principally in aqueous phase, hydrophobic polymer materials were selected for membrane preparation: polyvinylidene fluoride (PVDF), Hyflon (a perfluoro amorphous polymer), and polydimethylsiloxane (PDMS) (Fig. 1).

These polymers don't absorb in the region of interest of the catalyst; moreover, they are characterized by a high chemical, thermal, and UV stability.

In order to improve the catalyst/polymer interactions and to avoid catalyst leaching out from the membrane, lipophilic and insoluble-in-water derivatives of the decatungstate were employed: the tetrabutylammonium salt $((n\text{-C}_4\text{H}_9\text{N})_4 \text{W}_{10}\text{O}_{32})$ and a fluorinated decatungstate $([\text{CF}_3(\text{CF}_2)_7(\text{CH}_2)_3]_3\text{CH}_3\text{N})_4\text{W}_{10}\text{O}_{32})$ (Bonchio et al. 2003; Carraro et al. 2006).

A membrane-induced structure-reactivity trend, which may be exploited to achieve selective processes, was observed in polymeric catalytic membranes prepared embedding decatungstate within membranes made of PVDF (PVDF-W10), PDMS (PDMS-W10), or Hyflon (Hyflon-W10).

The polymeric catalytic membranes were prepared by solvent evaporation (to obtain dense membrane) or nonsolvent-induced phase separation (to obtain porous membranes). The decatungstate was solubilized or dispersed in the casting solution and heterogenized in the polymer matrix during the membrane formation process.

One of the crucial aspects during catalyst heterogenization is the maintaining of its structural integrity. Solid-state characterization techniques, including Fourier transform infrared (FT-IR) analysis and UV-vis spectroscopy in

diffuse reflectance, confirmed that the catalyst structure and spectroscopic properties were preserved within the membranes.

The PVDF-W10 and PDMS-W10 photocatalytic systems were used for the selective photooxidation of water-soluble alcohols (Bonchio et al. 2003). A membrane-induced discrimination of the substrate results from the oxidations of a series of alcohols with different polarity, through comparison with the homogeneous reactions.

The PVDF-W10 membranes were also successfully employed in the aerobic photooxidation of phenol in water carried out in a membrane reactor operating with flow through the membrane (Drioli et al. 2008).

Polymeric catalytic membranes were also prepared by immobilizing sodium decatungstate ($\text{Na}_4\text{W}_{10}\text{O}_{32}$) (Lopez et al. 2006; Lopez et al. 2007) and phosphotungstic acid ($\text{H}_3\text{PW}_{12}\text{O}_{40}$) (Fontananova et al. 2006), on the surface of PVDF membranes modified by Ar/NH_3 plasma discharges.

The groups grafted on the surface were able to bind the catalysts dissolved in aqueous solution, forming charge-transfer complexes.

Surface diagnostic techniques such as X-ray photoelectron spectroscopy (XPS), contact angle measurements (CA), and RX maps were used to attest the surface modification.

The catalytic membranes showed superior performances (higher reaction rate) compared to the corresponding homogeneous catalysts, in the photooxidation of phenol.

The decatungstate in the form of tetrabutylammonium salt was also heterogenized in Hyflon membranes by dispersion in the polymeric solution obtained using Galden HT55 (a mixture of perfluoro-hydrocarbons) as solvent and successive solvent evaporation. However, the insolubility of catalyst in this solvent and the low affinity between the catalyst and the polymeric matrix induced the formation of irregular catalyst aggregates, not well dispersed in the polymeric matrix, which tend to

precipitate toward the down surface (Carraro et al. 2006).

On the contrary, in the case of the fluororous-tagged decatungstate, SEM images of the membrane surface and cross section highlighted a homogeneous distribution of the catalyst domains which appear as spherical particles with uniform size.

The dimensions of these clusters and, as a consequence, the surface area and catalytic activity of the decatungstate were modulated acting on the membrane preparation conditions and catalyst loading.

The catalytic Hyflon-based membranes were tested in batch solvent-free oxygenation of benzylic C–H bonds of the ethylbenzene at 25 °C under O_2 atm.

The key observation was provided by an increase of the selectivity toward the alcohol (product of interest) and a higher turnover number (TON) when the catalyst was heterogenized in Hyflon membrane in comparison with homogeneous catalysts or the catalyst heterogenized in PVDF.

Decentralized Wastewater Treatment System

► Membrane Bioreactor for Decentralized Wastewater Treatment: A Case Study

Dechlorination Process

Zhi Wang

Chemical Engineering Research Center, School of Chemical Engineering and Technology, Tianjin University, Tianjin, China

Dechlorination process is the process to remove the chlorine from chlorinated compounds or water that has been chlorinated.

Dechlorination process has been widely used in water treatment, especially in the field of wastewater treatment and membrane process. Chlorinated compounds have been widely used as

refrigerant, agricultural fumigant, and solvent for metal degreasing and production of semiconductors in industrial processes for several decades (Kyunghoon and Woojin 2009). Chlorination has been used widely to disinfect wastewater prior to discharge. For these reasons, the chlorinated compounds and residual chlorine after disinfection are both contained in wastewater. However, the residual chlorine is toxic to many kinds of aquatic life, and the residual chlorine may also react with organic materials in the water forming chlorinated compounds, which have attracted an attention due to their carcinogenic and mutagenic characteristics. In membrane process, many kinds of membranes are also sensitive to residual chlorine, such as reverse osmosis (RO), nanofiltration (NF), and forward osmosis (FO). Consequently, dechlorination process is needed to remove the residual chlorine and degrade the chlorinated compounds.

The chlorinated compounds can be degraded by microbial and physical–chemical processes such as pump-and-treat, air sparging, and zero-valent iron passive barriers (Ma et al. 2003). The residual chlorine can be removed by absorption, chemical, and ultraviolet irradiation methods.

In membrane process, the feed must be dechlorinated to remove the residual chlorine and prevent the serious degradation of membrane chemical structure. Absorption and chemical methods are quite commonly used to dechlorinate in membrane process. The materials that have been proposed for dechlorination are granulated activated carbon (GAC), hydrogen peroxide (H_2O_2), ammonia (NH_3), sodium thiosulfate ($\text{Na}_2\text{S}_2\text{O}_3$), and the sulfur(IV) species: sulfur dioxide (SO_2), sodium bisulfate (NaHSO_3), sodium sulfite (Na_2SO_3), and sodium metabisulfite ($\text{Na}_2\text{S}_2\text{O}_5$) (George and Lynn 1984). Some of the important reactions of sulfite with residual chlorine species are:

The residual chlorine in membrane process should be controlled in a certain range, which should rely on the dechlorination process. At present, few options exist for reliable close-to-zero levels of residual chlorine in the water, and the residual chlorine is needed to prevent the membrane from fouling as well (Kim et al. 2009). The rate of chlorine attack to the membrane depends on various feedwater characteristics, like pH and temperature, and different membranes also have not alike chlorine tolerance therefore, the different kinds of feedwater and membranes decide the residual chlorine concentration needed should be different. In addition, the excess of oxidizing agents, like chlorine, not only oxidizes microbiology but also oxidizes other organic molecules into organic pieces and is converted into assimilable organic carbon (AOC), which is good food for the bacteria (Redondo and Lomax 2001). Consequently, the residual chlorine should be monitored and adjusted in dechlorination process.

Definition of Various Membrane Processes can be grouped according to the applied driving forces into: (1) hydrostatic pressure-driven processes such as reverse osmosis, nano-, ultra-, and microfiltration, membrane emulsification or gas separation, and pervaporation; (2) concentration gradient or chemical potential-driven processes such as dialysis, Donnan dialysis, pervaporation, and membrane contactors, such as membrane-based solvent extraction, membrane scrubbers and strippers, and osmotic distillation; (3) electrical potential-driven processes such as electrodialysis; and (4) temperature difference-driven membrane processes such as membrane distillation.

The molecular mixture which will be separated is referred to as feed, the mixture containing the components retained by the membrane is called the retentate, and the mixture composed of the components that have permeated the membrane is referred to as permeate (or filtrate in micro- and ultrafiltration). Table 1 lists the basic properties of membrane operations.

Definition of Various Membrane Processes, Table 1 Basic concepts of membrane operations

Process	Concept	Driving force	Mode of transport	Species passed	Species retained
Microfiltration (MF)		Pressure difference 100–500 kPa	Size exclusion, convection	Solvent (water) and dissolved solutes	Suspended solids, fine particulars, some colloids
Ultrafiltration (UF)		Pressure difference 100–800 kPa	Size exclusion, convection	Solvent (water) and Low-molecular-weight solutes (<1,000 Da)	Macrosolutes and colloids
Nanofiltration (NF)		Pressure difference 0.3–3 MPa	Size exclusion, solution diffusion, Donnan exclusion	Solvent (water), low-molecular-weight solutes, monovalent ions	Molecular-weight compounds >200 Da multivalent ions
Reverse osmosis (RO)		Pressure difference 1–10 MPa	Solution diffusion	Solvent (water)	Dissolved and suspended solids
Gas separation (GS)		Pressure difference 0.1–10 MPa	Molecular sieving, solution diffusion	Gas molecules having low-molecular-weight or high solubility diffusivity	Gas molecules having high-molecular-weight or low solubility diffusivity
Pervaporation (PV)		Chemical potential or concentration difference	Solution diffusion	High permeable solute or solvents	Less permeable solute or solvents
Electrodialysis (ED)		Electrical potential difference 1–2 V/cell pair	Donnan exclusion	Solutes (ions) small quantity of solvent	Nonionic and macromolecular species
Dialysis (D)		Concentration gradient	Diffusion	Solute (ions and low MW organics) small solvent quantity	Dissolved and suspended solids with MW >1,000 Da
Membrane contactors (MC)		Chemical potential, concentration difference, temperature gradient	Evaporation, diffusion	Compounds soluble in the extraction solvent; volatiles	Compounds non-soluble in the extraction solvent; nonvolatiles

(continued)

Definition of Various Membrane Processes, Table 1 (continued)

Process	Concept	Driving force	Mode of transport	Species passed	Species retained
Membrane-based solvent extraction (MBSX)		Chemical potential, concentration gradient	Diffusion partition	Compounds soluble in the extraction solvent	Compounds non-soluble in the extraction solvent
Membrane distillation (MD)		Vapor pressure gradient, temperature difference	Vapor transport	Water, solvent	Salts, nonvolatiles
Osmotic distillation (OD)		Vapor pressure gradient, hypertonic salt solution	Vapor transport	Water, solvent	Salts, nonvolatiles
Forward osmosis (FO)		Osmotic pressure	Diffusion	Water, solvent	Molecules, salts, ions
Supported liquid membranes (SLM)		Concentration gradient	Diffusion	Ions, low MW organics	Ions, less permeable organics
Membrane reactors (MR)		Various	Various	Permeable product/ controlled supply of reagent	Non-permeable reagents

Membrane dehumidification of atmospheric air

Dehumidification of atmospheric air represents one large application opportunity for advanced membrane technologies. Air is used to supply oxygen for a number of industrial processes.

Dehumidification of Atmospheric Air by Membrane Technology, Table 1 Comparison of different air dehumidification technologies

Technology	Working principle	Feature
Membrane dehydration	Removal of moisture through a selective membrane with minimal changes to air temperature and pressure	A steady-state, continuous process
		A selective membrane is needed
		A driving force needs to be provided for moisture to transport across the membrane
Water condensation	Cooling of humid air below dew point for moisture to condense as liquid water or ice	Cooling of whole air stream is necessary
		Condensation adds latent cooling duty
Adsorption or solid desiccating	Capturing moisture on a solid adsorbent	Solid materials are durable and do not generate any environmental emission
		Heat of adsorption is released during capture
		Saturated adsorbent has to be regenerated by increasing temperature and/or reducing partial pressure of water vapor, and both sensible and latent heat need to be supplied for desorption
		Regenerated adsorbent needs to be cooled to capture temperature and heat of adsorption is released during capture
Absorption or liquid desiccating	Capturing moisture in liquid fluid	Fluid can be readily moved around
		Same heating and cooling cycles as adsorption are needed for regeneration of saturated fluid

Moisture often needs to be removed when its presence presents a problem to downstream processes. For example, in oxygen production via cryogenic air separation, feed air needs to be adequately dehydrated to prevent formation of ice in the cooling equipment. Air dehumidification and conditioning in hot and humid climate are required to maintain comfort in buildings.

There are several commercial technologies for air dehydration, such as water condensation, solid adsorption, and liquid absorption. Their working processes and salient features are compared to membrane dehydration in Table 1.

As discussed above, the membrane dehydration is a steady-state process that works under feed air pressure and temperature. If humid air is cooled down or pressurized, moisture can be condensed out of the air as water. Cryogenic cooling of atmospheric air is often used in the industrial processes and in current building air conditioners for air dehydration. The main disadvantages of this method are the following: (i) the whole air stream has to be cooled down below water dew point and (ii) heat of condensation adds significant cooling duty. As a result, the energy efficiency is low. Solid adsorption and liquid absorption are widely used in the industrial gas and air drying

processes. A variety of solid adsorbents (e.g., silica gel, polymers, and zeolite) and liquid sorbents (e.g., LiCl, CaCl₂, and ethylene glycol) are available for capturing moisture at various temperatures and humidity levels. However, the desiccating material needs to be periodically regenerated by heating and cooling. The saturated desiccant is typically heated up to a much higher temperature than the capture to release the water as water vapor. Thermal energy has to be provided for the sensible heating and for compensating heat of desorption. After regeneration, the desiccant needs to be cooled down to the working temperature. During the capture process, heat of the adsorption (or absorption) is released to the dried air, which adds the sensible cooling duty of the air. Because of process complexity and significant thermal energy requirement, the adsorption or absorption method has found very limited applications in buildings.

Increasing energy demand in the building sector worldwide and growing concerns of indoor air quality have driven the development of new energy-efficient air dehumidification and conditioning technologies. Membrane dehumidification appears to be an attractive approach due to the following considerations. Different from

Dehumidification of Atmospheric Air by Membrane Technology, Fig. 1 Process scheme of dehumidification system

process industries, air in buildings does not need to get too dry, and high-degree dehumidification is not necessary. Membrane generally is effective for bulk separation. Membrane dehumidification does not generate any environmental pollution and is a green process. Lastly, membrane dehumidification has high thermodynamic energy efficiency.

One key challenge is the selective membrane. Due to handling of large gas flows and low partial pressures of water vapor in atmospheric air, the membrane has to be highly permeable to moisture. As expressed in the following equation, for a given dehydration rate (n_w) and partial pressure gradient of water vapor (Δp_w), the required membrane area decreases with increasing permeance in a reverse first order.

$$SA_m = \frac{n_w}{\text{Permeance} \cdot \Delta p_w}$$

Reducing usage of membrane area is not only beneficial to reduction of membrane cost but also enables a compact membrane module with minimal pressure drops for air to flow through.

The membrane also needs to have sufficiently high selectivity toward moisture over air. Air is non-condensable gas. As shown in the process flow of Fig. 1, any air leaked through the

membrane has to be pumped out of the water condenser into environment, while majority of the permeated water vapor is condensed. Thus, compression ratio for the leaked air is much greater than the permeated moisture, and air leakage would drastically increase power consumption of the vacuum pump. The previous study suggests that a H_2O /air separation factor above 200 be required for about 80 % dehumidification of 32 °C and 90 % RH air (Xing et al. 2013).

Other important factors about the membrane are durability and cost. The membrane has to be robust enough to be resistant to weathering, air contamination, and mechanical erosion in the duct. Also, the membrane surface has to be resistant to bacteria attachment and growth in warm and humid air environment. The membrane has to be cost-effective to penetrate the commercial building market.

Compared to extensive studies on membrane dehydration of water/alcohol mixtures, scientific publications on air dehumidification membrane development and tests are limited. Performance characteristics of a few membrane materials are compared in Table 2. The membrane permeance is given in both SI unit ($\text{mol}/\text{m}^2/\text{s}/\text{Pa}$) and gas permeation unit (GPU) for convenience of comparison. From an application point of view, the separation factor measured with actual humid air

^aThe selectivity was calculated as a ratio of relative permeability of single gas

is a meaningful parameter to quantify the membrane selectivity and calculate energy consumption. The separation factor was not reported in some of the literature. Instead, ratio of permeances measured with single gases was used to characterize the membrane selectivity. It should be alerted that such selectivity can differ drastically from the separation factor, because membrane structures and separation mechanisms under mixed gases could be substantially different from the single gas.

A NaA zeolite membrane supported on a thin porous metal sheet shows the highest H₂O permeance and excellent H₂O/air separation factor. These performance attributes of the NaA membrane can be explained by its microporous structure and molecular-sieving function. High selectivity is obtainable by eliminating or minimizing non-zeolite defects on the membrane. Since the selectivity results from selective H₂O adsorption at the entrance of zeolite pores, the membrane permeance can be proportionally

increased by reducing effective zeolite pore diffusion length without affecting the selectivity. The NaA framework is stable in air and various gas environments and is expected to possess excellent durability. It was reported that this kind of membrane enables development of compact membrane dehumidifiers with energy efficiency significantly higher than other dehumidification means at a competitive cost (Xing et al. 2013).

Dehydration

Wei Liu

Energy and Environmental Technology
Directorate, Pacific Northwest National
Laboratory, Richland, WA, USA

Dehydration is a common terminology but often has different meanings in different fields. In chemistry, dehydration is a chemical reaction process about conversion of one molecule into another one by removing H and O atoms as a water molecule, such as conversion of ethanol (C_2H_5OH) into ethylene (C_2H_4). In physiology and medicine, dehydration means the excessive loss of body water. Dehydration in food processing involves removal of water from various types of food for long-term preservation.

In the membrane field, dehydration generally refers to removal of water molecules from a water-containing fluid or mixture, i.e., it is a physical process. Two common membrane dehydration processes are illustrated in Fig. 1. In

pervaporation, water molecules are removed from water-containing liquid as water vapor and thus, a phase change of water occurs during the process. Due to significant heat of vaporization, the liquid feed temperature will be reduced without thermal energy inputs. Continuous supply of thermal energy is necessary to conduct pervaporation under a constant temperature. In the vapor-phase separation process, water vapor is separated out of a water vapor-containing fluid, and no phase changes are involved. Vapor-phase membrane separation is nearly an isothermal process.

The driving force for water molecules to move across the membrane is typically partial pressure gradient of water vapor. For a given feed fluid, partial pressure of water vapor in the permeate side can be lowered by pulling vacuum and/or introducing a sweep gas stream. Water transport across the membrane can also be driven by chemical potential gradient of water. For example, the forward osmosis process involves water transport from water-containing liquid of a lower solute concentration to liquid of a higher solute concentration, and a membrane gas/liquid contactor for gas drying involves transport of water from water vapor-containing gases into water-absorbing liquid. However, those membrane processes are viewed as different technologies from membrane dehydration.

There are a variety of applications for membrane dehydration. Dehydration is necessary for production of pure or anhydrous alcohols, because a water-alcohol mixture is often produced by fermentation or catalytic reactions from feedstock of sugars, corn, cellulose, or syngas. Ethanol fuel production represents one major application of dehydration technologies, and its worldwide production capacity reaches about 85 billion

D

liters/year in 2012. Successful development of cellulosic ethanol technologies is expected to lead more growth of ethanol fuels. Methanol is another commodity chemical with a large market. Water is miscible with a number of solvents and chemicals, such as acetic acid, acetone, and tetrahydrofuran. Dehydration of these solvents is involved in a range of industrial chemical conversion processes. The presence of water in industrial gases is ubiquitous. Air dehumidification and natural gas dehydration are examples of significant industrial gas drying processes.

One salient feature for the membrane dehydration process is molecular separation functions of the membrane. Removal of free water from slurry, i.e., separation of water from particulates, is typically referred as dewatering processes. The membrane allows permeation of water molecules while blocking other molecules. Because of the molecular separation function, the membrane dehydration provides significant advantages over conventional evaporation and gas drying technologies. The vapor-phase membrane separation is a steady-state process operating under constant temperature and pressure, as compared to periodic switches between adsorption (or absorption) and regeneration required for the solid (or liquid) desiccating process. For separation of a water-miscible liquid, the membrane dehydration is not limited by thermodynamic gas/liquid equilibrium such as co-boiling that often occurs in alcohol-water distillation processes. The membrane

dehydration is considered as an energy-efficient and compact process.

A number of membrane materials have been studied, and some of them are commercially developed for the dehydration application. They can be classified into two groups (Fig. 2): dense and microporous. The dense membrane provides selective absorption of water over other molecules. The separation mechanism can be described by the solute diffusion model. Most polymeric membrane materials fall into this category, which include polyvinyl alcohol (PVA), chitosan, alginate, polysulfone (PSF), polyimides, polyamides, polyaniline, and polyelectrolyte membranes such as cation-exchanged Nafion. Separation in a microporous membrane is mostly achieved through molecular sieving based on molecular sizes and/or selective adsorption of water at entrance of the membrane pore. Microporous zeolite, silica, and carbon are common membrane materials. Water molecule is often the smallest one in a mixture, and selective separation can be realized by making the membrane pore size small enough. However, the small pore size reduces molecule diffusion rates and may have a negative impact on flux. Molecular sieving based on selective water adsorption enables achievement of both high flux and selectivity (Zhang and Liu 2011). Some of zeolite frameworks, such as NaA, ZSM-5, and X-type and Y-type zeolite, have the pore size larger than that of water molecule but can be very selective toward water adsorption

over other molecules. Permeation of the other molecules is blocked due to adsorption of water molecules at the entrance of the zeolite pore, although the pore can be permeable to the other molecules in the absence of moisture.

The membrane dehydration performances are characterized by flux (J_w), permeance (P_w), and separation factor ($S_{w/i}$), which can be calculated from experimental measurements as follows:

$$J_w = \frac{\Delta n_w}{A_m \cdot \Delta t}$$

$$P_w = \frac{J_w}{p_{w,F} - p_{w,P}}$$

$$\alpha_{w/i} = \frac{(y_w/y_i)_P}{(x_w/x_i)_F}$$

where Δn_w is the amount of water collected in the permeate side of a membrane during a sampling period of time Δt , A_m is the membrane surface area exposed to the feed, $p_{w,F}$ is partial pressure of water in feed side, $p_{w,P}$ is partial pressure of water in permeate side, y_w and y_i are the respective molar fraction of water and specie i in the permeate side, and x_w and x_i are the respective molar fraction of water and specie i in the feed side.

The membrane materials and separation performances studied for the dehydration applications are well summarized in recent reviewing articles (Chapman et al. 2008; Wee et al. 2008; Bolto et al. 2012). The flux and separation factor reported for polymeric membranes are ranged from 0.01 to 1.0 kg/m²/h and from 10 to 1000, respectively, over a range of operation temperature from 25 °C to 80 °C. The microporous silica membrane has a higher flux and separation factor at comparable separation temperatures. The zeolite membrane shows the highest flux and separation factor. The flux and separation factor reported for separation of 10 wt.% water in ethanol with zeolite membranes (Zhang and Liu 2011) can be as high as 10 kg/m²/h and 10,000, respectively. The zeolite membrane can be used for both pervaporation at low temperatures and vapor-phase separation at high temperatures (above

100 °C). It should be noted that flux is a strong function of testing conditions. For a given membrane, water flux tends to increase with water content in the feed and with the separation temperature. Permeance should be a better parameter to characterize a membrane's throughput. However, this parameter was seldom reported in the literature. The permeance is estimated to vary over a wide range from 1.0E-5 to 1.0E-9 mol/m²/s/Pa among different membranes.

Selection of a suitable membrane for a given application depends on specific properties of the water-containing fluid. The material has to be chemically and physically stable under the separation conditions that the membrane structure can be maintained intact for a long time. For example, NaA is a commonly studied zeolite membrane for dehydration but it is not stable in acidic solutions. For dehydration of acetic acids, the more stable ZSM-5 and T-type zeolite materials are suggested. Pure zeolite membranes were considered difficult to prepare. To overcome the shortcomings with pure polymeric and ceramic membranes, researchers proposed mixed matrix membranes (MMM) comprising a polymeric base into which an inorganic material is dispersed and locked. The rationale is that some drawback associated with the polymeric material can be mitigated by incorporation of inorganic particles of durable structures, and MMM products may be produced with the manufacturing processes similar to polymeric membranes. There could be a variety of combinations from two groups of materials. Researchers have been actively exploring unique performance attributes of the mixed matrix membranes.

Membrane dehydration has found some industrial applications at relatively small scales so far. It is expected that widespread applications may become possible by lowering the membrane cost and enhancing productivity through continuing innovations.

Dehydration of Solvents with Membranes

Nora Jullok

School of Bioprocess Engineering, Universiti Malaysia Perlis (UniMAP), Arau, Perlis, Malaysia

Purification processes are required in the chemical industry in order to obtain a high purity of raw materials, intermediates, or end products. Separation of compounds from a mixture requires energy, and in many cases, the separation is difficult to perform due to the high energy consumption and high cost. The chemical or physical properties (e.g., molecular size, vapor pressure, freezing point, affinity, charge, density, and the chemical nature) of the target compounds are important factors in determining the viability of the separation process (Lee and Lai 1994; Mulder 1996). Solvent removal from dilute solutions via membrane filtration effectively leads to solute enrichment, but may just serve as a means to purify the solvent. Membrane processes are significantly advantageous in some applications (e.g., hemodialysis, azeotrope splitting, bioseparations, ultrapure water, fuel cells) while competing on equal terms with other traditional processes (Böddeker 2008). In membrane processes, the aim is to allow only one compound to pass through the membrane matrix while hindering penetration of other compounds. Reverse osmosis and pervaporation are the most common membrane processes for **dewatering of solvent**. In bioseparation, for instance, reverse osmosis membranes are capable of concentrating

bioorganic solutions under “mild” (low temperature) conditions by retaining aroma compounds. However, the principal and practical limitation which needs to be overcome is the osmotic pressure limitation. For example, the minimum pressure to dehydrate wine (11.9 % EtOH) by an ideally hydrophilic barrier is 64 bar; conversely, at least 860 bar is needed to remove pure ethanol from wine through an organophilic barrier. Removing water from the ethanol-water azeotrope (4 wt% H₂O at 78 °C) by reverse osmosis would require pressures in excess of 2000 bar; the other way around is meaningless (Böddeker 2008). As an alternative, pervaporation can be implemented. This process may involve a drastic reduction of the activity of the permeate by causing it to evaporate. Pervaporation can be potentially applied in the dewatering of organic liquid such as alcohols, ketones, and ethers among others. Although most of the installed solvent dehydration systems are applied for ethanol dehydration, dehydration of other solvents, including isopropanol, glycol, acetone, and methylene chloride, can be considered.

Dehydrogenation Reactions

Juergen Caro

Institut of Physical Chemistry and Electrochemistry, Leibniz University, Hannover, Germany

Dehydrogenations of aliphatic or cyclic hydrocarbons are under technical condition thermodynamically controlled, i.e., the reaction takes place near

Dehydrogenation Reactions,

Fig. 1 Principle of a 2-step oxidative ethane dehydrogenation in an oxygen-transporting membrane reactor with a perovskite membrane

at the equilibrium alkane $\rightleftharpoons$ olefin + H_2 . There are hundreds of papers describing an increase of the alkane conversion and an increase of the olefin yield, if hydrogen is removed through a hydrogen-selective membrane from the reactors. Numerous hydrogen-selective membranes have been evaluated in dehydrogenation reactions, most often Pd-based membranes as compact foils or supported thin layer, pure Pd or as alloy with Ag or Cu, zeolite-based membranes, but also metal oxide membranes prepared via the sol-gel route or carbon membranes prepared by pyrolysis. For details, see (Dittmeyer and Caro 2008; Caro 2010). Interestingly, besides alkane conversion and olefin yield, also the olefin selectivity increased in comparison with classical fixed or fluidized bed reactors since the removal of hydrogen suppresses hydrogenolysis.

However, for all membrane-supported dehydrogenation reactions with hydrogen removal, it was found that after an initial improvement of alkane conversion and olefin yield, because of the hydrogen drain-off, a severe coking of the catalyst and the membrane is observed which causes the conversion and yield to be after 30 min–2 h below those of a packed bed reactor. The development of coke-resistant catalysts and membranes could not compensate this negative influence. Therefore, the scientific interest in dehydrogenation reaction dropped dramatically within the last decade.

However, there is a new concept to support dehydrogenation reactions by a selective in situ combustion of the hydrogen using oxygen-transporting membranes according to

alkane + oxygen $\rightarrow$ olefin + water (steam) (Czuprat et al. 2009, 2010). The problem to be solved consists in the selective combustion of hydrogen in the presence of the alkane and olefin molecules. However, because of the higher reactivity of hydrogen in comparison with the hydrocarbons, this problem could be used, by using two catalysts: one catalyst for the dehydrogenation and the other one for the selective hydrogen combustion.

On the one-hand side, hydrogen is lost by combustion; on the other hand, in addition, in the boosting of alkane conversion and olefin yield, there are three advantages:

1. Hydrogen combustion brings heat for the endothermic dehydrogenation.
2. Steam suppresses coking of catalyst and membrane.
3. Steam dilutes the reactants which is favorable for thermodynamic reasons (shift of the equilibrium) (Fig. 1).

Dehydroisomerization of N-Butane to Isobutene

Ilaria Mirabelli

HyGear B.V. Westervoortsedijk, AV, Arnhem,
The Netherlands

Isobutene is a valuable intermediate in the petrochemical industry, used as a raw material in several commercial processes to produce, for instance, organic acid (methacrolein and methacrylic acid), fuel additive (ethyl *tert*-butyl and methyl *tert*-butyl ether), and rubbery materials (polybutene, isoprene). Isobutene can be

obtained as a by-product from an oil refining process (e.g., cracking for ethylene production) or produced by converting normal butane by means of a two-stage process, isomerization and dehydrogenation (Romanow-Garcia et al. 2007; Obenaus et al. 2005; Buonomo et al. 1997). Butanes can be isomerized to isobutane and then dehydrogenated to the corresponding olefin; alternatively, normal butane may first be dehydrogenated to normal butene and then, subsequently, isomerized to isobutene. The catalysts, reaction conditions, and technologies needed for each of these stages are different, setting thus an economic penalty to the composite two-stage process.

Some alternative ways to produce isobutene are by dehydration of isobutanol (also by enzymatic dehydration) and by fermentative route. Although biological isobutene formation is known since the 1970s, extensive metabolic engineering is required to achieve economically viable yields and productivities (van Leeuwen et al. 2012).

An interesting alternative to the two-stage process is a one-step process, allowing direct conversion of *n*-butane to isobutene by means of a *dehydroisomerization reaction* (United States Patent 3; Li and Iglesia 2008).

n-Butane dehydroisomerization (reaction III) involves two equilibrium reactions: dehydrogenation

of n-butane (reaction I) and skeletal isomerization to isobutene (reaction II); both equilibria limit the possible yield of isobutene (Pirngruber et al. 2000).

n-butane $\leftrightarrow$ n-butene + H ₂ $\Delta H_{\text{Reaction}}$ (@25 °C) = 130 kJ mol ⁻¹	(Reaction I)
n-butene $\leftrightarrow$ isobutene $\Delta H_{\text{Reaction}}$ (@25 °C) = -17 kJ mol ⁻¹	(Reaction II)
n-butane $\leftrightarrow$ isobutene + H ₂ $\Delta H_{\text{Reaction}}$ (@25 °C) = 113.7 kJ mol ⁻¹	(Reaction III)

It is believed that dehydroisomerization proceeds through a transient intermediate stage wherein normal butenes are produced which are then subsequently isomerized (United States Patent 4). Due to the endothermicity of dehydrogenation (reaction I), dehydroisomerization has to be carried out at high temperatures (above 400 °C). The reaction is favored at low pressure occurring with a mole number increase. Formation of by-products occurs as a consequence of some typical reactions side. Butane protolytic cracking over acid sites and hydrogenolysis over metal lead to methane, ethane/ethane, and propane/propene formation. Most of the by-products originate from secondary reaction of the butenes formed, which are significantly more reactive than butane.

To carry out the dehydroisomerization of n-butane to isobutene, two options have been taken into account: the first one involves the use of a two-bed system with a dehydrogenation catalyst in combination with an isomerization catalyst (United States Patent 5; Byggningsbacka et al. 1998). The other approach uses a bifunctional catalyst system. In the open literature, bifunctional noble metal(s)-modified acidic supports have been reported (Pirngruber et al. 1999; Derouane-Abd Hamid et al. 2000). It is generally assumed that the dehydrogenation is the primary reaction step which occurs over the metal sites; then the n-butenes produced are successively isomerized to isobutene over the Brønsted acid sites. These kind of bifunctional catalysts have to be optimized with respect to their dehydrogenation and isomerization activity, as well as their stability toward deactivation. Concentration of acid sites, metal loading, and metal dispersion are some key factors. In particular, it has been

found that n-paraffins can be dehydroisomerized to iso-olefins in a single step, by using a catalyst composition in which the support has low acidity. Metal dispersion affects the selectivity toward reaction products; high dispersion in the pores of the support seems to lead to a very low dehydrogenation activity and consequently to a lower n-butene and isobutene formation. Chromium or platinum catalysts have generally been employed for dehydrogenation. A number of solid acids, which includes ferrierite, SAPO (silicoaluminophosphates), alumina, and zeolites, can be used as support. Several zeolite-supported platinum catalysts, such as Pt-ZSM5, Pt-ZSM11, and Pt-MCM22, have been explored (Derouane-Abd Hamid et al. 2000; Bee Derouane-Abd Hamid et al. 2000; Gulin Selda et al. 2008; Megumu et al. 2002). Bimetallic/multimetallic systems on acid support (Pt,Re/[B]-ZSM-11, PtSn on SAPO-11) have been also investigated due to the fact that they may exhibit better catalytic performances than corresponding monometallic samples (Gulin Selda et al. 2008; Megumu et al. 2002; Ponc and Bond 1995; Bond 1991).

Research activity on dehydroisomerization reaction is going on, and, in the future, it can become a feasible alternative reaction route to produce isobutene.

Deionization by Membrane Operations

Maarten Biesheuvel

Wetsus, European Centre of Excellence for Sustainable Water Technology, Leeuwarden, The Netherlands

Deionization, or desalination, is the process in which salt ions are removed from a polar liquid, which is virtually always water. Water deionization and water desalination are generally considered as synonyms, though deionization can be applied in a more restricted sense to denote those

processes where during water treatment cations move in the one direction and anions in the other direction.

Of course, during deionization, the total removal rate of anions (times their charge number) must equal the total removal rate of cations (time charge), to keep the produced effluent water electroneutral (conserve electroneutrality). The condition of electroneutrality will hold both for the produced freshwater and for the produced concentrate, the brine.

To make ions go in different directions, deionization processes in the limited sense as defined above make use of electrical field effects, i.e., by applying an external current to a water flow cell or system, ions in the water are induced to move in the electric field, with cations moving to positions of lower electrical potential (i.e., in the direction of the field strength), while anions move in the opposite direction.

The most well-known membrane process for deionization is electrodialysis and the various modifications thereof, including electrodeionization, a process in which ion-exchange resin particles fill the water flow channels in between the ion-exchange membranes and electrodialysis reversal, a modification of electrodialysis in which the applied electrical current is temporarily reversed during short periods of time to abate biofouling and scaling on the membranes (Sonin and Probst 1968; Strathmann 2010; Nikonenko et al. 2010; Andersen et al. 2012).

A novel deionization technology making use of membranes is membrane capacitive deionization in which ion-exchange membranes are placed in front of porous electrodes (either in the form of freestanding membranes or as a coating on the electrode) to capacitively remove salt from water in a cyclic process, i.e., ions are temporarily stored in the electrodes in one phase of the cycle and are released again during the phase where a brine is produced (Lee et al. 2006; Li and Zou 2011; Biesheuvel et al. 2011; Nie et al. 2011; Zhao et al. 2012).

Dense Membranes

Fabio Bazzarelli, Lidietta Giorno and Emma Piacentini

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Dense membranes consist of dense structure presenting no detectable pore at the limits of electron microscopy. A mixture of molecules is transported through dense membranes by diffusion under the driving force of a pressure, concentration, or electrical potential gradient. Dense membranes may have a symmetric or an asymmetric structure (Fig. 1). The first type has a uniform composition and structure over the entire cross section, and the thickness of the entire

Dense Membranes, Fig. 1 Schematic drawing illustrating the **a** symmetric and **b** asymmetric structures of dense membranes

membrane determines the flux. These types of membranes are also named homogeneous (dense) membranes. The asymmetric membrane consists of thin and dense selective layer (skin) supported on a much thicker microporous support layer that provides mechanical support.

The surface layer performs the separation, and it is the principal barrier to the flow through the membrane (Strathmann et al. 2006). They can be prepared from a large number of different materials: inorganic (metals, ceramics) or organic (polymers).

Inorganic materials generally possess superior chemical, mechanical, and thermal stability relative to polymeric materials. However, these materials have the disadvantages of being very brittle and more expensive than the organic materials. The dense inorganic membranes, extensively studied in the past decade, include metallic membranes, primarily palladium alloy membranes used for hydrogen separation. Generally, there are three techniques for coating metallic thin films onto porous metallic or ceramic supports: electroless plating, chemical vapor deposition (CVD), and physical sputtering. Electroless plating is a method of metal plating by autocatalytic chemical reduction of the corresponding metal ions with simultaneous oxidation of a reducing agent. This technique can be applied for forming metal coatings even on nonconductive supports such as porous ceramic or glass. In CVD, a volatile component of coating materials is thermally decomposed on the surface of the heated substrate to form a thin film or coating. In physical sputtering, a thin continuous film is deposited on the porous substrate by the bombardment with high-energy particles on the support (Adhikari and Fernando 2006).

The dense polymeric membranes are produced mainly by phase inversion process and coating

technique. The phase inversion is a process where a polymer is transformed in a controlled manner from liquid to a solid state. The process of solidification is very often initiated by the transition from one liquid state into two liquids (liquid-liquid demixing). At a certain stage during demixing, one of the liquid phases (the high polymer concentration phase) will solidify so that a solid matrix is formed. The phase inversion can be induced by solvent evaporation, precipitation from the vapor phase, and thermal and immersion precipitation. Making dense membrane by coating involves a two-step process. One is the preparation of a suitable porous support obtained by phase inversion, and the second is the preparation of the barrier layer on the surface of the support. Several techniques can be used to apply a thin top layer on support such as dip coating, spray coating, spin coating, grafting, plasma polymerization, interfacial polymerization, and in situ polymerization to achieve these membranes (Mulder 1996). Coating technique is used to prepare thin and dense structure, possessing high flux.

Dense membrane is used mainly to separate components which are similar in size but have different chemical nature in processes such as reverse osmosis, gas and vapor separation, and pervaporation. The transport of gas, vapor, or liquid through a dense membrane can be described in terms of a solution-diffusion model. According to this model, permeant molecules are dissolved into the entrance face of the membrane and diffuse across the membrane matrix, then dissolved species are desorbed in the downstream face of the membrane. The reverse osmosis process uses a large pressure difference across the membrane to separate water from salt solutions. In pervaporation, the pressure difference across the membrane is small, and the process is driven by the vapor pressure difference between the feed liquid and the low partial pressure of the permeate vapor. Gas permeation involves transport of gases under a pressure or concentration gradient (Baker 2004). The separation of the various components of mixture is directly related to their transport rates within the membrane phase, which is determined by their diffusivities and concentration in the membrane matrix. Therefore, the performance of membrane is determined by intrinsic properties

Dense Membranes, Table 1 Applications of processes based on dense membrane

Type of process	Applications	Polymeric membrane
Reverse osmosis	Desalination of brackish water and seawater	Cellulose acetate
	Concentration of solutions of food products, pharmaceutical solutions, and chemical streams	Aromatic polyamide Sulfonated polysulfone
	Wastewater treatment	Polybenzimidazole
Gas separation	Separation of nitrogen from air	Polymers of intrinsic microporosity (PIMs) polydimethylsiloxane
	Removal of water from air	
	Recovery of hydrogen from ammonia purge gases	Perfluoropolymer Teflon AF 2400
	CO ₂ separation from flue gas streams	Polyimides
Pervaporation	Removal of volatile organic compounds from wastewater or gas streams	Polyurethane Polydimethylsiloxane
	Recovery of aroma and biofuels from fermentation broth	Poly(vinyl alcohol) Poly(vinylidene fluoride)
	Dehydration of organic solvents	

of materials. Table 1 summarizes some applications of processes based on dense membrane, and the most used polymeric membranes for each application are also reported.

Density Functional Theory Modeling of Membrane Systems

Giorgio De Luca

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Density functional theory is a new methodology in the frame of quantum mechanics (*ab initio*). The assessment of material features depending on the electron interactions or electron density polarization necessarily needs the use of quantum mechanics. Large molecular systems cannot be described with accurate quantum mechanical approaches, such as correlated Hartree-Fock (Szabo and Ostlund 1994), due to the huge computational time required by these. Instead, the density functional theory (Parr and Yang 1989) allows to get results with similar precision in relatively shorter computational time. Thus, density functional theory is a powerful tool to investigate large chemical systems like the nanostructures involved in the membrane preparation. In density functional theory, the total energy of an electronic system is evaluated through a total functional which depends on the electron density of the quantum system, $\rho(r)$, and external potential $v(r)$. It is defined as follows:

$$E_{\text{DFT}}[\rho(r)] = T_s[\rho(r)] + J[\rho(r)] + E_{\text{xc}}[\rho(r)] + \int v(r)\rho(r)dr$$

where $T_s[\rho(r)]$ is the kinetic energy of an isoelectronic noninteracting system, while $J[\rho(r)]$ describes the Coulomb electrostatic energy. The $E_{\text{xc}}[\rho(r)]$ is the exchange and correlation

functional, which takes into account the difference between the kinetic energies of the isoelectronic interacting and noninteracting systems in addition to the difference between the quantum electron-electron and Coulomb electrostatic energy. $\rho(r)$ can be evaluated by the nonlinear Kohn-Sham equations, defined by means of an *effective potential*. The electron density allows to calculate all the properties of the quantum system in addition to the total energy. Computational approaches, based on density functional theory, are applied in the study of catalysts used in membranes and in the study of noncovalent interactions, such as hydrogen-bonding and London dispersion interactions (De Luca et al. 2009). In fact, hydrogen-bonding, electrostatic interactions and London force are important for membranes at the basis of fundamental properties such as molecular adsorption and sorption, recognition, and self-assembly. Also size, shape, and electrostatic features of supramolecular architectures can be studied using density functional theory. All these properties control the selectivity of the materials, used in membranes, the permeability as well as the antifouling or anti-embrittlement features. Density functional theory studies of the catalysis in membrane reactors require the definition of structural models of the catalysts. For the most part, they are modeled by infinite surfaces, slabs, or different types of adsorbed or absorbed atomic clusters. These studies could be treated independently from the aforementioned analysis. However, it is important to emphasize that the merging of the results obtained by the different investigations would be advisable. For example, the kinetic constants characterizing a reaction path, related to a particular catalyst, evaluated by the density functional theory, should be compared with the diffusion coefficients characterizing the permeability of reagents and products through the membrane derived by the adsorption/absorption of different molecules.

Generally speaking, experiments are performed by investigators in virtually all applications of membrane processes, usually to discover something about a particular process or system. More formally, we can define an experiment as a test or series of tests in which purposeful changes are made to the input variables (also called factors) of a process or system so that we observe and identify the reasons for changes that may be observed in the output response (also called response variables or just response) (Montgomery 2001). Until now the extensively used strategy of experimentation in membrane field has been the one-factor-at-a-time approach. This method consists of selecting a starting point, or baseline set of levels, for each factor, then successively varying each factor over its range with the other factors held constant at the baseline level. After all tests have been performed, a series of graphs are usually constructed showing how

the response variables are affected by varying each factor with all other factors held constant. Figure 1 shows a set of these graphs in which the variation of permeate flux (J_p) is studied as a function of operating time, transmembrane pressure (TMP), feed concentration, and temperature.

Despite that this approach has been widely used, the major disadvantage is that it does not consider any possible interaction between the factors. An interaction is the failure of the one factor to produce the same effect on the response at different levels of another factor. In membrane processes interactions between factors are very common, and if they occur, the one-factor-at-a-time strategy will usually produce poor results. One-factor-at-a-time experiments are always less efficient than other methods based on a statistical approach.

In this regard, DOE can be defined as a systematic approach to understanding how factors affect the response variables such as efficiency, yield, or productivity. DOE uses a statistical methodology to analyze data and predict a response under all possible conditions within the limits selected for the experimental design. In addition, DOE allows to generate the required information in order to determine which factors and interactions are significant in contributing to the response being measured and those factors and interactions that are insignificant and do not contribute to either a particular response. As a matter of fact, the use of this approach allows to save time and money, minimizing the amount of experimentation (Wagner 2014).

DOE includes different classes of designs divided in three main groups such as mixture

Design of Experiment (DOE), Fig. 1 Typical examples of the one-factor-at-a-time strategy concerning the effect of operating parameters on the permeate flux

Design of Experiment (DOE), Fig. 2 Steps involved in design of experiment (DOE)

experiments, screening design, and response surface. Each design is used in specific situations to gather information from a particular set of independent variables. Mixture design can be used to optimize membrane characteristics (response variable) over different compositions of materials, solvents, additives, etc.

On the other hand, screening and response surface designs can be applied to study all the membrane processes, to get the main factors to control and the optimal process conditions, as well. Screening design is used to screen process and/or product variables, while response surface is used to get a better description of their curvature and interactions in the experimental space. Response surface approach, unlike factorial design, includes the quadratic term in the model; therefore it shows curvature.

DOE procedure involves several steps, as shown in Fig. 2.

Defining the problem may seem obvious, but in practice, it is sometimes difficult to do. In this step the aim of the study should be properly and clearly defined before starting any experiment. After the problem is properly defined, the second step in DOE framework is to select independent variables (factors), with their limits for evaluation, as well as dependent variables (responses to

measure for each experiment). The limits used in screening design, as well as response surface, are represented as 1 and -1 for the highest and the lowest value, respectively, and 0 for the middle value.

In membrane processes, some common independent factors include transmembrane pressure, temperature, flow rate, and membrane characteristics as well. On the other hand, permeate flux, rejection, and selectivity are common dependent variables or responses. Independent variables are normally quantitative in nature, meaning that they are set at a specific numerical value. However, in some experimental design, the independent variables are qualitative.

The quantity of experimental runs will depend on the quantity of selected factors as well as the type of design chosen. Experimental design creation produces all possible combinations of maximum, minimum, and middle values. Finally the investigator will obtain the quantity of experimental runs as well as the conditions for each experiment.

The experimental procedure, in which the investigator performs experimental runs according to the experimental design, is a critical step in DOE, because in this phase response variables data are collected for all the experiments or treatment combinations.

Once completed all the experiments and collected all the data for each response variables, data analysis can be performed. Generally the analysis is carried out by using statistic software in which the investigator should:

- Examine the presence of outliers and typos. In this step many graphs such as response distributions (histograms, box plots, etc.) and responses versus factors levels (main effect mean plots and interaction plots), can be constructed.
- Evaluate by means of ANOVA analysis the significance of each factor as well as interaction and quadratic effect (only for response surface designs).
- Create the model to describe the experimental data. The most common empirical models to fit the experimental data take either a linear form

(used in factorial design) or quadratic form (applied for response surface).

- Check the correlation coefficient (R^2) of the model, normal distribution of the residuals (error or noise), and autocorrelation (using Durbin-Watson statistic) as well.

Subsequently, the model can be used to give an answer to the questions fixed in the experiment objectives as well as to determine the optimal conditions to multiple responses.

Diafiltration

Zoltán Kovács

Department of Food Engineering, Institute of Bioengineering and Process Engineering, Szent Istvan University, Budapest, Hungary

Diafiltration (also called membrane filtration in dilution mode) is an operation mode of a pressure-driven membrane filtration process in which a diluant (pure solvent) is added into the process liquor in order to facilitate the separation of macrosolutes from microsolute.

Diafiltration may be performed either in batch (discontinuous) or continuous processing mode as schematically shown in Fig. 1. In both processing modes, diluant is added to and permeate is withdrawn from the system. The fundamental difference between the two configurations is that in

batch operation, the retentate stream is recycled into the feed tank where it is mixed with the content of the reservoir and with fresh diluant. The concentration of membrane-permeable microsolute in the feed tank decreases over time, and the final product is obtained directly in the feed reservoir when operation is terminated. In contrast, continuous processing is performed in a flow-through manner with both permeate and retentate being withdrawn. Thus, batch diafiltration is a dynamic process in which the composition of fluid stream fed into the membrane module is a function of time, while continuous diafiltration is essentially a static (steady-state) process in which the feed stream is of constant composition.

The benefits and disadvantages offered by the two processing modes in industrial-scale ultrafiltration (UF) systems have been summarized by Lipnizki et al. (2002) as shown in Table 1.

Diafiltration has found a vast number of industrial applications in the chemical, pharmaceutical, environmental, biotech, and food and beverage sectors. The requirement for an effective separation is the utilization of a membrane that has a high rejection for macrosolute but allows the passage of microsolute. The mass transport, unlike in dialysis, is driven by pressure differences across the membrane. Depending on the particular application, either the retentate or the permeate is the valuable phase of economic importance (or both), and the applied membrane can be a microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), or reverse osmosis (RO) membrane. Some typical applications include:

- MF: enzyme recovery from fermentation broths; cell harvest and debris removal; separation of casein from serum milk proteins
- UF: protein purification and buffer exchange; ethanol removal from human serum albumin obtained from blood plasma; fruit juice clarification; milk fractionation; Kraft black liquor treatment; recovery of small molecules (e.g., amino acids, antibiotics, organic acids, etc.) from fermentation broth
- NF: desalination of dyes and optical brighteners; partial demineralization of whey; production of desalted and concentrated

Diafiltration, Fig. 1 Schematic flow diagram. (a) Batch diafiltration. (b) Continuous diafiltration

Diafiltration, Table 1 Comparison of batch and continuous diafiltration (Adopted from Lipnizki et al. 2002)

	Batch	Continuous
UF plant investment	Low	High
Batch tank investment	High	Low
Control investment	Low	High
Space requirement UF	Low	High
Space requirement tank	High	Low
Feed volume flexibility	High	Low
Antibiotic/protein concentration in permeate	Variable	Constant
Residence time	High	Low
Temperature flexibility	Low	High
Module efficiency	Low	High
Energy consumption	High	Low

- antibiotics; desalination of gelatin for improved color and whipping properties
- RO: solvent replacement in herb extracts; beer dealcoholization

Diafiltration is also called *membrane filtration in dilution mode* in accordance with the terminology recommendation of the former European Society of Membrane Science and Technology (now known as the European Membrane Society) (Gekas 1988). Although the latter term is less frequently used in the literature, it better reveals that an operation *mode* of a *filtration process* is considered.

Membrane filtration plants are rarely designed exclusively for microsolite removal. Most

applications require a simultaneous microsolite removal (i.e., macrosolute purification) and macrosolute concentration (i.e., feed volume reduction). In many cases, the term *diafiltration* stands for a process that is designed to achieve these dual objectives. In continuous processing, the different modes of operation (i.e., concentration and dilution modes) are assigned to different stages which are connected in series. In batch processing, the targeted twin aims of concentration and fractionation are obtained either in consecutive operational steps (e.g., in traditional diafiltration, intermittent feed diafiltration, sequential dilution diafiltration) or applying specific diluant utilization strategies (e.g., variable-volume diafiltration, dynamic-volume diafiltration). Overall, these characteristics of diafiltration put it in a favorable position in comparison with other separation techniques and even with a sequence of competitive unit operations (Jönsson and Trägårdh 1990).

In discontinuous diafiltration processes, including both dilution and volume reduction methods, one must specify both the level of volume reduction/dilution in each stage and also the number of stages so the diafiltration factor is not so easily, or meaningfully, defined in those instances.

Diafiltration Factor

Greg Foley

School of Biotechnology, Dublin City University, Dublin, Ireland

One of the most commonly used methods of diafiltration is constant volume diafiltration (CVD) also known as continuous diafiltration. In this process, diluant is added to the retentate solution which is undergoing batch ultrafiltration. The process is set up so that the rate of addition of the diluant exactly balances the permeate flow rate – hence the retentate volume is constant. For any given solute with apparent rejection coefficient, σ , the solute concentration declines during a CVD process according to the equation (Cheryan 1998)

$$c = c_0 e^{-(1-\sigma)V_b/V_s}$$

where V_b is the volume of diluant (buffer) added while V_s is the solution (i.e., retentate) volume. The ratio V_b/V_s is termed the diafiltration factor, sometimes referred to as the number of diavolumes. Once the rejection coefficient is known, this quantity completely specifies the reduction in solute concentration that will be achieved during CVD.

Dialysis

Emma Piacentini, Lidietta Giorno and Fabio Bazzarelli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Dialysis is a process in which small solutes diffuse from a high concentration solution to a low concentration solution across a semipermeable membrane until equilibrium is reached (Strathmann 2006; Mulder 1996). From a liquid solution containing the solvent and molecular components of different molecular weight or sizes (feed solution), the components diffuse through the membrane into the solvent referred as dialysate or “stripping” solution under the force of a concentration difference (Fig. 1). Dialysis process is normally operated in a countercurrent configuration and involves the use of nonporous membrane.

Membrane materials most often used include regenerated cellulose, cellulose acetate, polysulfone, polycarbonate, polyethylene, polyolefin, polypropylene, and polyvinylidene fluoride.

There are different forms of dialysis depending on the components of the feed solution and the structure of the membrane. The most simple form of dialysis is the diffusion of neutral molecules;

Dialysis, Fig. 1 Schematic representation of dialysis process operated in a countercurrent configuration

instead when the electrolytes are separated with neutral membrane or with charged membrane, the process is called Donnan dialysis.

When the feed solution contains neutral molecules, the transport in dialysis is described by the Fick's law:

$$J_i = D_i \frac{dC_i}{dx}$$

where J_i is the rate of transfer of component i or flux, dC_i/dx is the concentration gradient of component i , and D_i is the diffusion coefficient that is a measure of the mobility of the individual molecules.

When feed solution contains an electrolyte which consists of a cation and an anion with significantly different diffusivities, an electrical potential gradient will be created. This potential gradient is referred as diffusion potential, and although it might be very small, it will slow down the faster diffusing ion and speed up the slower ion so that both ions will diffuse with the same velocity. Because the membrane does not carry fixed charges, all ions of the electrolyte are transported in the same direction even if their diffusion coefficient is quite different. In this case, the transport is described by the following equation:

$$J_s = \frac{D_a D_c (z_a + z_c)}{D_a z_a + D_c z_c} \frac{dC_s}{dx}$$

where J_s is the rate of transfer of salts or flux, dC_s/dx is the concentration gradient of salt s , and D_a and D_c are the diffusion coefficients of anion a and cation c , respectively.

The situation becomes more complex if the feed solution contains more than one electrolyte and if the membrane carries fixed charges. There are two forms of coupled transport (Fig. 2):

- Cocurrent or diffusion dialysis (Fig. 2a) when co- and counterions are transported in the same direction
- Countercurrent or Donnan dialysis (Fig. 2b) when no counterions permeate the membrane and co-ion fluxes are in an opposite direction

In the cocurrent coupled transport (Fig. 2a), the feed solution, containing the component A^- (i.e., Cl^-) as anion and B^+ and C^+ (i.e., Na^+ and H^+) as cations, is separated by an anion-exchange membrane, from a solution containing the component A^- as anion and only C^+ as cation. If the concentration of specie AB (i.e., $NaCl$) is assumed to be much higher in the feed solution than in the other solution, while the concentration of AC (i.e., HCl) is supposed to be lower in the feed solution than in

Dialysis, Fig. 2 Schematic diagram illustrating (a) cocurrent coupled and (b) countercurrent transport

D

the other solution, the anion A^- can pass through the membrane from the feed solution to the other solution as a consequence of the concentration gradient. Because of the electroneutrality requirement, an anion can permeate the membrane only when accompanied by a cation. The only cation able to permeate through the membrane by using a specific carrier is C^+ that is transported against their concentration gradient. In the countercurrent coupled transport (Fig. 2b), the feed solution, containing the component A^- (i.e., Cl^-) as anion and B^+ and C^+ (i.e., Na^+ and H^+) as cations, is separated by a cation-exchange membrane, from a solution containing the same components. If the concentration of species CA and BA (i.e., HCl and NaCl) in the feed solution is assumed to be much higher than in the other solution, the anion A^- cannot pass through the membrane, while the cation C^+ moves from feed solution to the other solution and B^+ in the opposite direction against its gradient concentration.

Dialysis process is mainly used to separate low molecular weight components from those of high molecular weight. The major application of dialysis is the artificial kidney; in this application the

blood of a person with a kidney failure is treated in a dialysis process to remove toxic small molecular weight metabolites such as urea, creatine, uric acid, and others. During the treatment, the blood flows on one side of the membrane, whereas dialyzing fluid, which contains vital salts such as sodium, potassium, and calcium that may not be removed from blood, flows on the other side. The small organic solutes diffuse through the membrane, and the process is continued until the concentration of the toxic components has been reduced to a certain level. Other applications are the recovery of caustic soda from colloidal hemicellulose during viscose manufacture and removal of alcohol from beer. Also in biotechnology and pharmaceutical industry, the process is used to remove salts from bioproducts and for fractionation.

Dielectric Exclusion Model in Membranes

Veronica Silva

Dow Water and Process Solution Division at The Dow Chemical Company, Boulevard Cecilia Grierson 355, Buenos Aires, Argentina

Introduction

Dielectric exclusion has been recognized in the last two decades as one important mechanism for ion separation in membranes with fixed charges in the active surface as it is the case of NF membranes. They are manufactured to selectively reject a specific ion or ion groups, which was achieved by the inclusion of functional groups (charges) in the membrane active layer. These charges produce an additional rejection due to electrostatic phenomena that hinder the movement of charges through the membrane. Consequently, NF membranes allow the rejection of ions when their size is much lower than the pore size.

The rejection of the target compounds has been studied to occur in two main mechanisms:

- Partitioning mechanisms: steric effect, Donnan equilibrium, and dielectric exclusion; which occur in the interfaces of the active layer.
- Transport mechanisms: convection, diffusion, and electrokinetic effects; which occur through the active layer thickness length.

The phenomenological models available in literature always include the transport mechanisms through the Nernst-Planck simplified equation but not all of them have been implemented with all the partitioning mechanisms recognized year to date. In some cases, dielectric exclusion has been neglected. NF models have four parameters:

1. The ratio (active layer thickness)/(active layer porosity): $\Delta x/A$. It is obtained using Hagen-Poiseuille law.
2. The active layer mean pore radius: r_p . It is usually obtained from experiments of retention

of neutral solutes, atomic force microscopy (AFM), or liquid-liquid porosimetry (Otero et al. 2008).

3. The volumetric charge density: X . It can be inferred by the tangential streaming potential (TSP) technique, where the zeta potential and the surface charge density on the top surface of the membrane are measured and then, assuming that this charge is representative of the selective layer of the membrane, the value of X can be calculated (Martínez et al. 2002). However, a concentration gradient appears through the membrane and X is correlated with this gradient as long as the separation takes place. Thus, a charge gradient has to be considered as well. In a recent work, a Freundlich isotherm was included to correlate X with ion concentration (Silva et al. 2011).
4. Dielectric constant inside the pores: ϵ_p . It can be obtained by impedance spectroscopy technique or by mathematical modeling of designed experiments.

Dielectric Exclusion Model

At the feed and permeate interfaces a thermodynamic equilibrium takes place and a difference of solute concentration (c_i) is generated from one side to the other at each interface. These concentration leaps can be described as:

$$\frac{c_{i,0}}{c_{i,m}} = \phi_i \frac{\gamma_{i,m}}{\gamma_{i,0}} \exp(-z_i \Delta \Psi) \exp(-\Delta W'_{i,B}) \times \exp(-\Delta W'_{i,im}) \quad (1)$$

for the $x = 0$ interface and similarly for the $x = \Delta x$ interface.

In this equation all partitioning effects are included: ϕ_i takes into account the steric effect, the deviation from the ideal bulk solutions at both sides of the membrane is taken into account through the activity coefficients $\gamma_{i,m}$ and $\gamma_{i,0}$; and $\Delta \Psi$ represents the Donnan potential.

The dielectric exclusion is accounted in the terms: $\Delta W'_{i,B}$ for the Born contribution and

$\Delta W'_{i,im}$ for the effect of the image forces (Yaroshchuk 2000). The expressions typically used for these dielectric effects are shown in Box 1.

In the Born effect, a difference between the dielectric constants of the bulk solution (ϵ_b) and the solution inside the pore (ϵ_p) exists as a result of confinement effects. Therefore, to transfer the ions from the bulk solvent to the membrane is necessary to make an extra work that can be estimated using Born equation (Eq. 2) and assuming that ϵ_p must be lower than ϵ_b .

The image force effects appear when two media of different dielectric constants, like a membrane matrix and an electrolyte solution, are in contact and the interaction of ions with the electrical charges induced by the ions at the interfaces causes a dielectric exclusion. The interaction with a polarized interface is well known as “image force” in analogy to the interaction with a fictitious image charge located at the other side of the interface, at the same distance from it than the real charge. The sign and magnitude of the image are determined by the dielectric constants of the media. Consequently, the exclusion due to image force effect depends on the difference between the dielectric constant of the membrane matrix (ϵ_m) and the solution inside the pores.

Equations 1, 2, 3, 4, 5, 6, 7, and 8, have to be introduced the more global a complex NF model for the resolution where ϵ_p appears as only fitting parameter (or coupled with X). A resolution algorithm can be found in specific literature for NF modeling (Yaroshchuk 2000).

Nowadays, all authors are in agreement that dielectric effect must be used to characterize the rejection of ionic solutions. But, there is still controversy if Born or image force effects are more suitable for NF. The Born effect has been used by many authors (Bowen et al. 1997; 2002) neglecting the image force effects, since the small NF pores make the ϵ_p value close to the

one of the membrane, reducing the effect of image forces within the pores while increasing the solvation energy barrier. In that case, Eq. 2 is used as an approximation to obtain the dielectric exclusion effect.

Box 1: Dielectric Exclusion Mathematical Model

The dielectric Born energy ($\Delta W_{i,B}$)

$$\Delta W'_{i,B} = \frac{(z_i e)^2}{8\pi\kappa_B T \epsilon_0 a_s} \left(\frac{1}{\epsilon_p} - \frac{1}{\epsilon_b} \right) \quad (2)$$

Where a_s is the cavity radius defined by Rashin and Honig (Rashin and Honig 1985) as the distance from the center of the ion to the point where the dielectric constant becomes different than the vacuum one, ϵ_0 .

The dielectric image force energy ($\Delta W_{i,im}$)

This effect depends on the geometry of the pores,

$$\Delta W'_{i,im} = \frac{2\alpha_i}{\pi} \int_0^\infty \frac{K_0(k)K_1(v) - \beta K_0(v)K_1(k)}{I_1(v)K_0(k) + \beta I_0(v)K_1(k)} dk \quad (\text{Cylindrical geometry}) \quad (3)$$

$$\Delta W'_{i,im} = -\alpha_i \ln \left[1 - \left(\frac{\epsilon_p - \epsilon_m}{\epsilon_p + \epsilon_m} \right) \exp(-2\mu) \right] \quad (\text{Slit-like geometry}) \quad (4)$$

Where,

$$\alpha_i = \frac{(z_i F)^2}{8\pi\epsilon_0\epsilon_p RT N_A \Gamma_p} \quad (5)$$

$$v = \sqrt{\kappa^2 + \mu^2} \quad (6)$$

$$\mu = Fr_p \sqrt{\sum_i \frac{z_i^2 c_{i,m} \phi_i (\gamma_{i,m}/\gamma_{i,0}) \exp(-z_i \Delta\Psi - \Delta W'_{i,B} - \Delta W'_{i,im})}{RT \epsilon_0 \epsilon_b}} \quad (7)$$

$$\beta = \frac{\kappa}{\sqrt{\kappa^2 + \mu^2}} \left(\frac{\epsilon_m}{\epsilon_p} \right) \quad (8)$$

The K_0 , K_1 , I_0 , I_1 are the modified Bessel functions, ϵ_m is the dielectric constant of the dry polymer of the membrane, which is usually a constant value obtained from bibliography

- presence of an applied electric field (Cosgrove 2010; Hunter 2001). The ratio of the dielectric permittivity of a material to that of a vacuum ($\epsilon_o = 8.85 \times 10^{-12}$ F/m) is defined as the dielectric constant (k). Water has a dielectric constant of 80.1 at 20 °C; this large value reflects the highly polar nature of water.
- The dielectric permittivity appears in a number of important equations describing the surface charge and electrostatic interactions in membrane systems. For example, the membrane zeta potential (a measure of the membrane surface charge) can be evaluated from the measured streaming potential (E_z) using the Helmholtz-Smoluchowski equation:

$$\left(\frac{E_z}{\Delta P} \right) = \frac{\epsilon \zeta}{\eta A_o}$$

where ΔP is the pressure difference across the membrane, η is the solution viscosity, ζ is the zeta potential, and A_o is the solution conductivity (Burns and Zydney 2000).

The distance over which the electrical potential varies in an electrolyte solution is described by the Debye length (λ_D), which provides a measure of the thickness of the electrical double layer (Hunter 2001):

$$\lambda_D = \left[\frac{F^2}{\epsilon RT} \sum Z_i^2 C_i \right]^{1/2}$$

where F is Faraday's constant, R is the ideal gas constant, T is the absolute temperature, and z_i and C_i are the valence and concentration, respectively, of each ion in solution.

Differential Scanning Calorimetry in Membrane Characterization

Annarosa Gugliuzza

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The differential scanning calorimetry (DSC) is a thermodynamic technique that measures the difference in heat flow between sample and related reference against time or temperature, while programming the sample temperature under specific atmosphere conditions (Haines 1995). The sample is contained in a pan and the reference is the related empty pan. There are two kinds of calorimetric techniques, including:

- Heat flux DSC, where sample and reference are heated in the same furnace and a difference of temperature (ΔT) is measured. Successively, the signal is converted to a power difference by the calorimetric sensitivity.
- Power-compensated DSC, where both the sample and reference are heated in two independent heaters, while the electrical power ($\Delta P = d(\Delta Q/dt)$), requested to maintain close to zero the difference of temperature between sample and reference, is measured in real time.

The energy flux is associated with a transition or reaction and is graphed as a heat flow along the ordinate, while the temperature or time is the abscissa. In DSC curve, the endothermic peak is associated with absorption of power, while the exothermic peak implies release of power from the sample. The verse of the peaks depends on the sign of the heat flow.

DSC allows studying different events, including phase transitions, glass transition, and

Differential Scanning Calorimetry in Membrane Characterization, Table 1 Thermal transitions and related parameters measurable by DSC

Event	Phase transition	Energy sign	Parameter
Fusion	<i>sol</i> → <i>liq</i>	Endothermic	λ , DH

Chemical reactions		Exothermic/endothermic	DH

chemical reactions. For each thermal event, thermodynamic magnitudes such as latent heat (λ), specific heat (C_p), and/or a variation of enthalpy (ΔH) can be calculated (Table 1).

The transitions studied for polymers and compounds at low molecular weight can also be examined for related membranes (Gugliuzza and Drioli 2003). DSC plays a relevant role in materials science and membrane technology, because it permits to identify the best-performing materials through the identification of structure-transport relationships that form the base of the membrane performance (Gugliuzza and Drioli 2004). History, molecular rearrangements, and interactions are some critical issues to be taken in account when a membrane is processed (Yang et al. 2000). In this respect, DSC analysis can provide useful indication about structural features of the samples enabling the design of new interfaces with superior performance in prospect.

Figure 1 shows typical transitions studied on polymeric membranes, including the glass transition (T_g) that is displayed as a change in the baseline due to a variation of C_p of the polymer forming the membrane.

All amorphous polymers exhibit a T_g ; below this temperature value, the membrane becomes glassy owing to the inability of the polymer segments to rotate and rearrange themselves. When the membrane temperature is increased over its T_g , an increase in energy and free volume is observed due to a broader mobility of the chains,

Differential Scanning Calorimetry in Membrane Characterization,

Fig. 1 Main endothermic and exothermic transitions observable by DSC

which enters the polymer in the rubbery region. Heating and cooling rates as well as chain relaxation can affect T_g value and shape, respectively.

The fusion is another endothermic event involving crystalline domains distributed through the membranes. The amount and extent of these ordered regions depends on the chemistry, molecular weight, and thermal history of the samples. Polymorphism and crystalline features of the membranes can be examined in relation to transport properties and mechanical stability as well. If the polymer forming the membrane is available to crystallize, a release of energy is associated with a decrease in heat flow. The study of crystallization is often more useful than fusion, because it allows distinguishing peaks that normally cannot be well visible in melting.

Phase separation, miscibility, and compatibility of polymer binary blends, copolymers, and, more generally, composites are among the most interesting events to examine by DSC (De Lorenzo et al. 2012). In this case, the ability of the materials to interact and distribute themselves in continuous and uniformly interlaced spaces can be evaluated under different experimental conditions. Other interesting indication about the membranes solidity can be achieved from the study of curing, aging, as well as degradation and oxygen stability. All these parameters can significantly affect the membrane transport properties.

Diffusion Coefficient

Boguslaw Kruczek

Department of Chemical and Biological Engineering, University of Ottawa, Ottawa, ON, Canada

Introduction

The diffusion coefficient (or ► [diffusivity](#)) is a measure of mobility of a species (atom, molecule, or ion), which depends on the frequency with

which a species moves and the size of each movement. The magnitude of diffusion coefficient is governed by the restricting forces of the medium in which diffusion takes place. The diffusion coefficient is typically associated with, but not limited to, ► [Fick's laws](#) of diffusion. It is generally prescribed to a pair of species. For a multicomponent system, it is prescribed for each pair of species in the system, and diffusion in multicomponent systems is described by the Stefan-Maxwell equation. In a binary system either species can be mobile, or one species can be mobile while the other immobile. The example of the latter is diffusion in porous and nonporous membranes. The diffusion coefficient in membrane governs the membrane permeability and selectivity.

Diffusion Coefficient of Liquid in Porous Membrane

In the case of liquids, the effective diffusion coefficient of solute i in membrane (D_{ei}) is related to the ordinary molecular diffusion coefficient (D_i) in liquid by (Seader et al. 2011)

$$D_{ei} = \frac{\varepsilon D_i}{\tau} K_{ri} \quad (1)$$

where ε and τ are membrane porosity and tortuosity, and K_r is the restrictive factor, which depends on the solute diameter (d_m) and the pore diameter (d_p):

$$K_r = \left[1 - \frac{d_m}{d_p} \right]^4, \quad \frac{d_m}{d_p} \leq 1 \quad (2)$$

When $d_m > d_p$, $K_r = 0$ and the solute cannot diffuse through the pore, which is referred to as size exclusion. In the absence of size exclusion and a hydrostatic pressure gradient across the membrane (the example of such process is diffusive dialysis), the selectivity for the separation of solutes i and j is

$$\alpha_{ij} = \frac{D_i K_{ri}}{D_j K_{rj}} \quad (3)$$

► [Molecular diffusivity](#) of solutes in liquid is estimated using well-established correlations (Seader et al. 2011). For large solutes that can be approximated as rigid spheres diffusing at infinite dilution through a stationary solvent, D_i is predicted from the theoretical equation of Stokes-Einstein. On the other hand, the diffusion coefficients of small solutes at infinite dilution are estimated using the empirical equation of Wilke-Chang or more modern Hayduk and Minhas correlations. In the case of dissolved salt, acid, or base, the diffusing entities are ions. In the absence of an electric potential, the infinite-dilution diffusivity of single salts in an aqueous solution is estimated from the Nernst-Haskell equation.

Diffusion Coefficient of Gas in Porous and Microporous Membranes

The diffusion coefficient of gas in porous membranes depends on the mean free path of the gas molecules (λ):

$$\lambda = \frac{3\mu}{2P} \left(\frac{\pi RT}{2M} \right)^{1/2} \quad (4)$$

where μ is the gas viscosity, T is the absolute temperature, R is the universal gas constant, P is the pressure, and M is the molecular weight of the gas. When $d_p/\lambda \ll 1$, i.e., the collisions with pore wall are much more frequent than the collisions with other gas molecules, the transport is dominated by Knudsen diffusion, and the

► [Knudsen diffusion](#) coefficient of species i in a straight cylindrical pore is given by (Seader et al. 2011)

$$D_{Ki} = \frac{d_p}{3} \left(\frac{8RT}{\pi M_i} \right)^{1/2} \quad (5)$$

In the other extreme when $d_p/\lambda \gg 1$, the ordinary molecular diffusion prevails, and the corresponding molecular diffusivity can be estimated using a theoretical equation of Chapman and Enskog or a more practical semiempirical equation of Fuller, Schettler, and Giddings.

When d_p is comparable with λ , the effective diffusion coefficient of solute i is

$$D_{ei} = \frac{\varepsilon}{\tau} \left[\frac{1}{(1/D_i) + (1/D_{Ki})} \right] \quad (6)$$

In microporous membranes ($d_p < 2$ nm) and particularly in ultramicroporous membranes ($d_p < 0.7$ nm), d_m becomes comparable to d_p , and one of the two possible transport mechanisms is the activated Knudsen diffusion, and the corresponding diffusion coefficient is given by (Shelekhin et al. 1995)

$$D_{AKi} = \frac{d_p}{3} \left(\frac{8RT}{\pi M_i} \right)^{1/2} \exp \left(\frac{-\Delta E_i}{RT} \right) \quad (7)$$

where ΔE_i is the activation energy for diffusion of species i , which rapidly increases as d_p approaches to d_m . On the other hand, when $d_p \gg d_m$, ΔE_i approaches to zero and Eq. 7 simplifies to Eq. 5.

The D_{Ki} , D_{ei} , and D_{AKi} (5–7) are generally referred to as D_{gas} , which is related to the permeability coefficient (P_{gas}) by

$$P_{gas} = \frac{D_{gas}}{RT} \quad (8)$$

Consequently, the selectivity for the separation of gases i and j is solely determined by the ratio of the diffusivity coefficients, which varies depending on the pore size of the membrane. If molecular diffusion dominates, the membrane has no selectivity. If Knudsen diffusion dominates, the selectivity is limited to the square root of the ratio of the molecular weights of solutes j and i . On the other hand, if the activated Knudsen diffusion prevails, very high selectivities are possible (Shelekhin et al. 1995).

Diffusion Coefficient in Nonporous Membranes

The transport of species in nonporous membranes is described by ► [solution-diffusion mechanism](#),

in which the ► [permeability coefficient](#) is the product of the diffusion coefficient and the ► [solubility coefficient](#) (S_i):

$$P_i = S_i D_i \quad (9)$$

Consequently, membrane selectivity is a product of the solubility-selectivity (α_s) and the diffusivity-selectivity (α_D), where the latter is the ratio of the diffusion coefficients. The diffusion coefficient along with P_i , and S_i are considered to be the intrinsic property of the membrane material (Kesting and Fritzsche 1993).

Nonporous membranes are generally formed from synthetic organic polymers; they can be also formed from metals. Diffusion in metal membranes is limited to diatomic gases, which first dissociate and dissolve according to ► [Sieverts' Law](#) and then diffuse as individual atoms through the membrane (Burggraaf 1996). In the case of polymer membranes, the solute does not dissociate before dissolving in the membrane. Consequently, the size of diffusing solutes in polymer membranes may vary considerably. In turn, since the diffusion coefficient strongly depends on the molecular weight of solute, the diffusion coefficients in polymer membranes vary by many orders of magnitude. The effect of the molecular weight on the diffusion coefficient is stronger in ► [glassy polymers](#) than in rubbery polymers (Kesting and Fritzsche 1993).

For a given family of polymers, the diffusion coefficient of solute depends on the fractional free volume of polymer (v_f) according to (Baker 2012)

$$D_i = A \exp \left(\frac{B}{v_f} \right) \quad (10)$$

where A and B are adjustable parameters. Despite the fact that v_f in glassy polymers, which ranges from 15 % to 20 %, is greater than that in rubbery polymers (10–15 %), the diffusivity in rubbers is generally greater than that in glasses. The diffusion coefficients in rubbery polymers range from 10^{-13} to 10^{-8} m²/s. The upper values of this range are comparable to those of molecular diffusion in liquids. The diffusion coefficients in glassy

polymers range from 10^{-18} to 10^{-8} m²/s. The upper values are comparable and sometimes exceed those in the rubbery polymers. This is because of some glassy polymers; in particular ► **polymers with intrinsic microporosity (PIMs)** have extraordinary large v_f (up to 35 %) despite a very rigid polymer backbone (Baker 2012). Generally greater diffusivity in rubbery polymers arises from the fact that portions of the polymer chains can freely move due to thermal motions, and segments of the polymer backbone can also rotate around their axis. On the other hand, thermal motion in glasses is limited. Strong interactions between solute and polymer chains may increase the chain mobility. As the concentration of interactive solute increases, membrane plasticization may occur, leading to increase in the diffusion coefficient of solute (Kesting and Fritzsche 1993).

Diffusion in nonporous membranes is an activated process, and consequently, the diffusion coefficient in both glassy and rubbery polymers increases with temperature according to Arrhenius-type relation (Seader et al. 2011):

$$D_i = A_i \exp\left(\frac{-E_i}{RT}\right) \quad (11)$$

where A_i is a pre-exponential constant which depends among other on the nature of the solute and E_i is the activation energy for diffusion of solute i . Eq. 11 is similar to Eq. 7.

Diffusion Dialysis

Heiner Strathmann

Universität Stuttgart, Institute of Chemical Process Engineering Stuttgart, Baden-Württemberg, Germany

Diffusion dialysis with ion-exchange membranes is mainly used today to recover acids or bases from a mixture with salts. The process is based on the fact that ion-exchange membranes generally show a high permeability for counterions while being more or less impermeable for co-ions. Exceptions are protons and hydroxide ions which can easily permeate both cation- and anion-exchange membranes. The transport mechanism in diffusion dialysis is more complex than in conventional dialysis due to the electrostatic interaction between positive and negative charges and the electroneutrality requirement (Kobuchi et al. 1987). The process and equipment design is very similar to that used in conventional dialysis. In diffusion dialysis, the driving forces for the transport of ions through the ion-exchange membrane are gradients in their chemical potentials only. There is no external electrical potential applied. The principle of the process is illustrated in 1 showing part of a diffusion dialysis stack for the recovery of HCl from a salt mixture. It is composed of anion-exchange membranes forming cells in which in alternating series a feed solution of an HCl/FeCl₂ mixture and a stripping solution of water is introduced. Since anion-exchange membranes are permeable for H⁺, Cl[−] and H⁺ permeate the membranes, while the other cations (Fe²⁺) are retained (Fig. 1).

The mass transport in diffusion dialysis is determined by the transport of ions and can be determined by the respective mass balance equations described in the literature. A typical application of diffusion dialysis is the recovery of acids from spent pickling solutions used in the metal industry. A typical diffusion dialysis plant is shown in the process flow diagram of Fig. 2. A stack with 100–200 cell pairs is operated with

Diffusion Dialysis,

Fig. 1 Schematic drawing illustrating the principle of diffusion dialysis utilizing anion-exchange membranes to recover an acid from a mixture with salts

**Diffusion Dialysis,**

Fig. 2 Flow diagram of the diffusion dialysis process

countercurrent flow of the feed and the stripping solutions, which allows high acid recovery rates.

The flow diagram shows a feed solution containing an acid and a salt which often is the effluent of metal surface treatment procedure. This solution is fed by a pump from a reservoir into a dialyser stack which contains only anion-exchange membranes. A stripping solution, which generally is water, is pumped in countercurrent flow into the stack. During the pathway through the stack, the acid diffuses from the feed solution through the anion-exchange membrane into the

stripping solution and leaves the system as salt-free product. The salt is retained and leaves the stack as waste. The main application of diffusion dialysis is in the treatment of spent metal surface pickling solutions (Strathmann 2010; Oh et al. 2000).

whereas pore flow in meso- and macroporous membranes. Consequently, membrane processes such as gas separation (GS), pervaporation (PV), and reverse osmosis (RO) are governed by diffusion, or more precisely the solution-diffusion mechanism, whereas ultrafiltration (UF) and microfiltration (MF) by the pore flow mechanism.

Diffusion in Membranes

Boguslaw Kruczek

Department of Chemical and Biological Engineering, University of Ottawa, Ottawa, ON, Canada

Introduction

Diffusion is the net movement of a substance (atom, ion, or molecule) from a region of high concentration to a region of low concentration. In the case of membranes, diffusion along with pore flow is the main transport mechanism. Diffusion dominates in dense and microporous membranes

Diffusion in Dense Membranes

Polymeric membranes have generally a dense structure with no visible pores (they are also referred to as nonporous membranes). Molecules permeate through transient free volume elements between polymer chains. A molecule entrapped in a cavity between the polymer chains bounces around the cavity walls and eventually jumps to an adjacent cavity once transient opening for the molecule passage appears. Molecular dynamic simulations, which allow calculations of the fluctuations in the volume between polymer chains due to thermal motion, have been used to visualize diffusion of gases in polymers (Baker 2012). Figure 1

Diffusion in Membranes,

Fig. 1 Motion of a carbon dioxide molecule in a 6FDA-4PDA polymer matrix (Reprinted from Smit et al. (1992). Copyright Elsevier (permission pending))

shows motion of a carbon dioxide molecule in a 6FDA-4PDA polymer matrix. The molecule bounces around the cavity in the first 100 ps and it does not move more than 5 Å, which is indicative of the cavity size. Then, thermal motion moves a segment of the polymer chain allowing the molecule to jump to an adjacent cavity, where it remains until another movement of the polymer chain allows it to jump to another cavity (Baker 2012). The diffusion coefficient (D) in polymer membranes is therefore defined (Koros and Fleming 1993):

$$D = \frac{f\lambda_d^2}{6} \quad (1)$$

where f is the average jump frequency and λ_d is the average jump length. The smaller the molecule the more frequent jumps between the cavities. However, in addition to the size, the shape of the molecule is also very important. For example, carbon dioxide is known to be much more diffusive in polymer membranes than methane even though carbon dioxide has a slightly greater molar volume than methane. On the other hand, methane is a spherical molecule with a kinetic diameter of 3.72 Å, while the molecule of carbon dioxide is an oblate ellipsoid 5.25 Å long, but with the diameter of only 3.03 Å. Consequently, as carbon dioxide molecule bounces around in a cavity it occasionally becomes oriented in such a way that it can jump through a gap between the polymer chains as small as 3.03 Å. Such a small gap would not permit jumping of the methane molecule (Baker 2012).

As temperature increases, the thermal motions of polymer chains allowing the molecule to jump from one cavity to the other become more frequent, and also the molecule bounces faster with a cavity, which means that once a transient opening of appropriate size becomes available, it will more likely jump into the adjacent cavity. Experimentally observed dependence of D in polymeric membranes on temperature follows the Arrhenius relationship (Burggraaf 1996):

$$D = D^* \exp\left(\frac{-\Delta E_a}{RT}\right) \quad (2)$$

where ΔE_a is the activation energy for diffusion, D^* is a preexponential factor often related to the entropy of activation and the average jump length, and R and T are the universal gas constant and the absolute temperature, respectively. Diffusion process in which D follows Eq. 2 is referred to as an activated diffusion. The activation energy for diffusion in polymeric membranes is positive; thus, the greater the ΔE_a the smaller the D ; also it indicates that D increases with T , which is consistent with molecular dynamics simulations. In turn, ΔE_a is directly proportional to a cohesive energy density (CED), which is indicative of strength of attractive forces between adjacent polymer chains. The CED increases when polar and hydrogen bond groups are present in polymer chains (Koros and Fleming 1993).

Diffusion in Microporous Membranes

Microporous membranes have permanent pathways (pores) for transport of molecules. They are generally made from inorganic materials such as zeolites, carbonized polymers, and amorphous silica; however, organic membranes made from polymers with intrinsic microporosity (PIM), such as polytrimethylsilylpropyne (PTMSP), are also considered as microporous (Baker 2012).

The three most common diffusion mechanisms in microporous membranes, shown in Fig. 2, include activated diffusion (small pores), surface diffusion (intermediate pores), and Knudsen diffusion (large pores). The exact pore size ranges for a given diffusion mechanism are determined based on the difference (W) between the potential energy outside the pore (E_{out}) and the potential energy within the pore (E_{in}) (Thornton et al. 2010).

As a molecule approaches a pore opening, each atom in the gas molecule interacts with every atom from the pore wall through van der Waals forces. The potential difference is also referred to as a suction energy; because a positive W translates to a force sucking the molecule from outside to inside of the pore (adsorption), while a negative W results in a force repulsing the

Diffusion in Membranes,
Fig. 2 Diffusion mechanisms in microporous membranes (Reprinted from Thornton et al. 2010. Copyright John Wiley & Sons. (permission pending))

Diffusion in Membranes,
Fig. 3 Potential energy difference for a single oxygen molecule at the entrance of a carbon cylindrical pore (Reprinted from Thornton et al. 2010. Copyright John Wiley & Sons. (permission pending))

molecule from the pore. The activated transport takes place when $W < 0$, and the activation energy for diffusion in Eq. 2 corresponds to $\Delta E_a = |W|$ (Thornton et al. 2010).

Figure 3 presents an example of the potential energy difference as function of pore size (d) for a single oxygen molecule entering a cylindrical carbon pore from outside environment, in which $E_{\text{out}} = 0$. The pore diameter corresponding to $W = 0$ is referred to as a minimum pore size (d_{min}), while the pore diameter corresponding to $W = RT$ represents Knudsen diameter (d_K). Activated diffusion occurs when $d < d_{\text{min}}$, surface diffusion dominates when $d_{\text{min}} < d < d_K$, while

Knudsen diffusion dominates when $d > d_K$. Table 1 summarizes d_{min} and d_K for different gases in carbon and silica pores with two different pore geometries.

Activated Diffusion Versus Surface Diffusion

When transport is dominated by activated diffusion, there is no adsorption and membrane permeability (P) is solely governed by the diffusion coefficient, i.e.:

Diffusion in Membranes, Table 1 Minimum pore size for the activated transport ($d_{\min}$) and minimum pore size for Knudsen diffusion (d_K) at room temperature (298 K). All pore sizes are given as the PAS pore size^a (Adapted from Thornton et al. 2010)

^aPositron annihilation spectroscopy (PAS) diameter $d' = d - \delta d$, where δd is the electron cloud thickness surrounding the surface atoms ($\delta d = 3.32$ Å)

$$P = P^* \exp\left(\frac{-\Delta E_a}{RT}\right) = P^* \exp\left(\frac{-|W|}{RT}\right) \quad (3)$$

where ΔE_a is the activation energy for diffusion, which is identical to ΔE_a in Eq. 2, which is equal to the absolute value of the potential difference. On the other hand, when transport is dominated by surface diffusion, membrane permeability (P_s) is governed by both the diffusion coefficient (D_s) and the solubility coefficient (S_s). The latter is a thermodynamic factor that correlates the concentration of molecules in the adsorbed phase to the external pressure, which typically follow a Langmuir isotherm. At the same time, S_s follows Arrhenius relation:

$$S_s = K_o \exp\left(\frac{q}{RT}\right) \quad (4)$$

where q (>0) is a heat of adsorption, which implies that S_s decreases with temperature. Surface diffusion is an activated process, which depends on q :

$$D_s = D_s^* \exp\left(\frac{-aq}{RT}\right) \quad (5)$$

where a is a proportionality constant ($0 < a < 1$). The product aq is the activation energy for surface

diffusion, which represents the energy barrier separating two adjacent sorption sites (Thornton et al. 2010). Since $P_s = D_s S_s$, combining Eqs. 4 and 5 leads to:

$$P_s = P_s^* \exp\left(\frac{(1-a)q}{RT}\right) \quad (6)$$

The term, $(1-a)q$ is positive; therefore, P_s , unlike P , decreases with temperature. In the case of dense polymeric membranes, the permeability coefficient is also a product of the diffusivity and the solubility coefficients, and the latter, similarly to the surface diffusion solubility coefficient, decreases with temperature. On the other hand, the corresponding increase in diffusivity overcompensates a decrease in solubility. Thus, the permeability coefficient in dense polymeric membranes follows Arrhenius-type relationship similar to the permeability coefficient for activated diffusion in microporous membranes.

The third diffusion mechanism, Knudsen diffusion, is not an activated process. Although Knudsen diffusion coefficient increases with temperature, it does not follow Arrhenius-type relationship (Thornton et al. 2010).

Diffusive Flow

Boguslaw Kruczek
Department of Chemical and Biological
Engineering, University of Ottawa, Ottawa, ON,
Canada

Introduction

Diffusive flow (► [diffusive transport](#)) refers to the transfer of matter by diffusion. Quantitative study of diffusive flow dates back to the nineteenth century to the works of Thomas Graham and Adolf Fick. The latter was formulated to what is now known as Fick's first law of diffusion:

$$J = -D \frac{\partial c}{\partial z} \quad (1)$$

where J is the diffusive flux, D is the diffusion coefficient, and c is the concentration of species transported by diffusive flow and z is a coordinate along which the net diffusive transport occurs. The diffusive flow is therefore a concentration gradient-driven process, with the net mass transfer from high concentration to low concentration region. Diffusive flow may occur along with a convective flow. For a binary system (A , B), the

total flux of component A (N) relative to a fixed frame of reference is

$$N_A = J_A + y_A N = J_A + y_A (N_A + N_B) \quad (2)$$

where y_A is a mole fraction of A in the binary mixture at a given point. If component B is stationary ($N_B = 0$), for example, when A is transported across a membrane, then

$$J_A = N_A (1 - y_A) \quad (3)$$

Fick's first law of diffusion is limited to binary systems. Therefore, if diffusive flow of a binary mixture takes place across a membrane, counting the membrane as a stationary component, the system is ternary. For ternary and more generally multicomponent systems, diffusive transport is described by the Stefan-Maxwell equation. Diffusive flow is the main transport mechanism in several membrane separation processes, including ► [gas separation](#), ► [pervaporation](#), reverse osmosis, and diffusive dialysis.

Driving Force for Diffusive Flow

Fick's first law implies that the driving force for diffusion is the concentration gradient. In the simplest example of diffusive flow in membranes – ► [Knudsen diffusion](#), which occurs in porous membranes in which the collisions between gas molecules and pore walls are more frequent than those between the gas molecules – the concentration gradient is expressed in terms of the partial pressure gradient for binary and multicomponent system and as a total pressure gradient for the single gas transport. However, in the more rigorous analysis, the true driving force is the gradient of chemical potential. Assuming applicability of the ideal gas law, a more general expression for the flux of component A is given by Kärger et al. (2012):

$$J_A = u_{AC_A} = -\frac{RT}{f} \frac{d \ln p_A}{d \ln c_A} \frac{dc_A}{dz} \quad (4)$$

where u_A is the flow velocity of component A , f is a friction coefficient, R is the universal gas constant, T is the absolute temperature, and p_A is the partial pressure of component A . The term $d \ln p_A / d \ln c_A$ represents the gradient of the equilibrium isotherm in logarithmic coordinates, which is a thermodynamic correction factor. This term may vary substantially with concentration, but in general, at low concentrations (i.e., when c_A is a linear function of p_A), it approaches unity. Comparison of Eq. 1 with Eq. 4 reveals that

$$D_A = \frac{RT}{f} \frac{d \ln p_A}{d \ln c_A} \quad (5)$$

This expression for the diffusion coefficient arises from the interpretation of the diffusive flow as being driven by the gradient of chemical potential and opposed by frictional forces.

Maxwell-Stefan Equations

The Maxwell-Stefan model was originally developed to describe diffusion in homogeneous gas or liquid phase. It considers the diffusion coefficients as inverse drag coefficients representing the interchange of momentum between the different types of molecules. The general form of the Maxwell-Stefan equation for diffusion in a multicomponent mixture is (Kärger et al. 2012)

$$\frac{c_i}{RT} \frac{\partial \mu_i}{\partial z} = \sum_{j \neq i} \frac{c_i J_j - c_j J_i}{c \mathcal{D}_{ij}} \quad (6)$$

where $J_i = u_i c_i$ is the diffusive flux of the i -th component, $\mathcal{D}_{ij}$ represents the Stefan-Maxwell diffusivities, and c is the total concentration. For an ideal gas, the left-hand side of Eq. 6 reduces to $\partial c_i / \partial z$, so for equimolar counter-diffusion in a binary system

$$J_i = -J_j = -\mathcal{D}_{ij} \frac{\partial c_i}{\partial z} \quad (7)$$

which is identical with the usual Fickian formulation given by Eq. 1. The difference between the Fickian and Maxwell-Stefan diffusion coefficients

is that the later takes into consideration the interactions between components i and j , which in dilute systems are negligible. Consequently, the Fickian and Maxwell-Stefan diffusion coefficients are equivalent in dilute ideal systems. On the other hand, they deviate from each other in concentrated systems. However, Fickian diffusion coefficient is known to be a function of concentration in concentrated systems.

Solution-Diffusion Model

Diffusive flow or diffusion is a rate-limiting step in membrane processes such as gas separation, pervaporation and reverse osmosis, in which the transport is governed by the solution-diffusion model (Baker 2012). In this model, it is assumed that penetrant in feed and in feed-side interface of the membrane and the penetrant in the permeate-side interface and permeate are in instantaneous equilibrium. The corresponding equilibrium constant, which is referred to as distribution coefficient or a solubility coefficient (S), is a thermodynamic factor. The solubility coefficient is constant only at low concentrations where the concentration of penetrant in the membrane is a linear function of its concentration in the fluid phase (e.g., Henry's law is applicable). In this case, the diffusive flux can be expressed in terms of the external driving force, for example (Koros and Fleming 1993),

$$J = SD \frac{(p_f - p_p)}{L} = P \frac{(p_f - p_p)}{L} \quad (8)$$

where $P = SD$ is the permeability coefficient, p_f and p_p are the partial pressures of penetrant at the feed and permeate sides, respectively, and L is the membrane thickness. Equation 8 is applicable for gas permeation; however, similar rate equations can be written for reverse osmosis and pervaporation.

Dual-Mode Sorption

Most of practical membranes are made from glassy polymers in which sorption does not follow

linear isotherm according to Henry's law, but rather the so-called ► [dual-mode sorption](#) in which (Kesting and Fritzsche 1993)

$$c = c_D + c_H = Sp + \frac{c'_H bp}{1 + bp} \quad (9)$$

where c_D is the concentration in the Henry-type sites, c_H is the concentration in the Langmuir sites, b is the hole affinity constant, and c'_H is the hole saturation constant, which is a measure of the sorption capacity of the unrelaxed volume. Equation 9 is essentially the summation of Henry and Langmuir isotherms. The molecules in Langmuir sites are partly or completely immobilized; however, the two populations i.e., those in Henry sites and those in Langmuir sites, are in instantaneous equilibrium. Assuming partial immobilization of molecules in Langmuir sites leads to the dual-mobility model, which accounts for two distinct molecular environments with different diffusion coefficients. Consequently, Fick's first law for dual-mobility model becomes

$$J = -D \frac{\partial c_D}{\partial z} - D_H \frac{\partial c_H}{\partial z} \quad (10)$$

where D and D_H are the diffusion coefficients in Henry and Langmuir sites, respectively. Introducing $F = D_H/D$, which varies from 0 (complete immobilization) to 1 (no immobilization in Langmuir sites), and substituting the expressions for Henry and Langmuir isotherms, Eq. 10 can be rearranged to Kesting and Fritzsche (1993):

$$J = -D \left(1 + \frac{FK}{(1 + \alpha c_D)^2} \right) \frac{\partial c_D}{\partial z} \quad (11)$$

Equations 9, 10, and 11 are applicable to single gas permeating through the glassy polymeric membranes. They are easily extendable to binary and multicomponent systems within the classical Fickian diffusion formalism (Zolondz and Fleming 1992), without resorting to Maxwell-Stefan equations.

However, the Maxwell-Stefan formulation has the important advantage that the rate parameters are simply related to directly measurable

quantities, thus making this approach more suitable for use in the correlation of experimental and predictive models (Kärger et al. 2012). This approach has become quite popular for the analysis of diffusive transport in inorganic adsorbent membranes, in which adsorption is described by, but not limited to, Langmuir isotherm, largely because of the work of Krishna and his associates (Wesselingh and Krishna 2000). Nevertheless, because of its simplicity compared to the Maxwell-Stefan formalism, solution-diffusion model based on Fickian diffusion is still by far the most commonly used approach to analyze diffusive transport in membranes.

Diffusive Transport

► [Diffusivity](#)

Diffusivity

Renzo Di Felice
University of Genova, Genova, Italy

Synonyms

[Diffusive transport](#); [Molecular diffusivity](#)

For a species in a homogeneous phase, gas, liquid, or solid, diffusivity can be defined as any material transport driven by concentration difference. Its physical origin lies in the random molecular motion that leads to an overall phenomenon of smoothing concentration gradients: any batch systems originally showing concentration difference for one or more species will eventually be completely mixed if enough time is elapsed. Diffusivity is easily quantified by the diffusivity flux, i.e., by how much a species diffuses per unit area per unit time.

There are various practical situations which for different reasons, both theoretical and practical, have received particular attention and have been investigated in depth. A brief summary is given here (Cussler 1997).

- Molecular diffusivity. In this case, the fluid where the phenomenon is taking is considered unbounded so that there is no physical interaction between the diffusing species and the system boundaries. Moreover, the species are considered to be diluted so that any interaction between the diffusing molecules can also be neglected. This is probably the most studied cases, and many systems can be considered to fall in these categories.
- Diffusivity of strong electrolytes. As before here we considered the system to be unbounded. However, there is an interaction between the diffusing molecules which affects the transport rate and must be taken into account.
- Diffusivity of associating solutes. The solute associates to form aggregates (weak electrolytes or micelle), and again this affects the transport rate.
- Solvation. Solute-solvent interactions cannot be ignored in this case.
- Solute-boundary interactions are important: here we can have diffusion in porous media or composite, diffusion in cylindrical pore (Knudsen or surface or capillary or molecular sieving).

Digital Reconstruction

It is a procedure to represent the internal structure of materials in digital form, usually, binary, in three dimensions using data from microphotographs or other sources of spatial correlation data. It has contributed significantly to the visual comprehension of the internal configuration of porous materials, human tissues, and composite materials. In the case of porous materials, like porous membranes, catalyst supports, rocks, etc., a binary representation in three dimensions assigns the value of 0 (or 1) to the voxels that lie in the void space and the value of 1 (or 0) to the voxels in the complementary space (solid) (Torquato 2002, 2010). In this way, one obtains a fully three-dimensional array of flags (0 or 1) that defines in a discretized form the pore space inside the material. This array can then be utilized in simulations of sorption and transport phenomena (Gelb 2009), typically, diffusion, flow, two-phase flow, and dispersion that are of utmost importance in the design and modeling of membrane materials and membrane separation processes. Raw data for the initiation of the reconstruction procedure can be obtained in various ways. Physical serial sectioning along planes that are normal to a fixed direction has repeatedly been used using special microtomes or surface grinders following impregnation of the void phase with some suitable substance (resin, Wood's metal, etc.). Digitization of the photographs of each and every section of the material provides a set of two-dimensional arrays to be combined in a deterministic fashion into a three-dimensional array that discretizes the working sample of the medium. Computer tomography provides the same type of information in an automated or semiautomated manner and enjoys

Digitized Structure

Model, Fig. 1 Stochastic reconstruction of porous material using the fractional Brownian motion method, showing individual volume elements

D

tremendous use in medicine and some types of porous media, most typically in hydrocarbon reservoirs. More recently, stochastic techniques are attracting the increasing interest of investigators in this area inasmuch as they require a single section only rather than a whole series of sections. Provided that the sample is sufficiently isotropic and homogeneous, one can extract valuable geometric and topological data from the section and reconstruct in three dimensions a discretized form of the material that respects the features that characterize the two-dimensional image of the section (Quiblier 1984; Adler 1992). Such features include various moments of the correlation function, typically porosity and autocorrelation function, but also higher-order moments or lineal-length distribution, chord-length distribution, etc. The latter is succeeded by the simulated annealing technique (Kirkpatrick et al. 1983) that, theoretically, is capable of reproducing three-dimensional descriptions of materials from an arbitrary number of moments of the correlation function at the expense, of course, of heavy requirements in computational time. A simpler procedure that has proven efficient for several types of porous membranes including asymmetric ones is the so-called fractional Brownian motion technique that respects the first two moments of the correlation function and, in addition, offers an

interweaving option that allows three-dimensional reconstruction (Fig. 1) at much greater scale than the correlation length of the structure (Kikkinides and Burganos 2000). For materials that have evolved from powders through some agglomeration or sintering process, ballistic or random placement methods can be used that allow mass transfer between coalescing particles at a controlled fashion so as to reproduce the actual grain-size distribution and porosity or solid fraction. Reconstruction of fiber-type materials can proceed in a similar manner. In the case of porous membranes that contain nanoscale pores, scattering techniques can be used that offer in an implicit manner the autocorrelation function, thus sidestepping the stage of microscopy and the subsequent phase of image analysis for the extraction of two-dimensional features.

Diluant

Greg Foley

School of Biotechnology, Dublin City University, Dublin, Ireland

Any diafiltration process involves the replacement of solvent (including undesired impurities) with a liquid of desired composition. This liquid is known as the diluant. For example, in constant volume diafiltration (CVD), also known as continuous diafiltration, diluant is added to a tank of unpurified solution while it undergoes batch ultrafiltration. The rate of diluant addition is set equal to the permeate flow rate, and thus the solution (retentate) volume remains constant. The effect of this process is the gradual replacement of the solvent and any solutes with low rejection coefficients with the diluant. Mathematically, the reduction in concentration of any solute, with rejection coefficient, σ , is given by

$$c = c_0 e^{-(1-\sigma)V_d/V_s}$$

where V_d is the volume of diluant added and V_s is the solution (retentate) volume. The ratio V_d/V_s is known as the diafiltration factor.

The diluant may be purified water or, more likely, a buffer.

Dip-Coating Method for Ceramic Membrane Preparation

Zhaoliang Cui

State Key Laboratory of Materials-Oriented Chemical Engineering, College of Chemistry and Chemical Engineering, Nanjing Tech University, Nanjing, China

Dip-coating method for ceramic membrane preparation is one of the most important methods for ceramic membrane preparation. It is usually employed to form the intermediate layer of a ceramic membrane (Lindqvist and Lidén 1997). The procedure is illustrated in Fig. 1 (Li 2007). The drying process starts simultaneously when the substrate is in contact with an atmosphere with a relative humidity below 100 %. In a multiple step process, after calcination of the first layer, the complete cycle of dipping, drying, and calcination is repeated. The raw material is a more

Dip-Coating Method for Ceramic Membrane Preparation, Fig. 1 Dip coating (Li 2007)

interactive powder than the materials used for the support and the porosity is governed by the choice of sintering temperature. The viscosity of the particle suspension and the coating speed or time are the critical factors in dip-coating process (Lindqvist and Lidén 1997). By this method, pore size of the coating layer is possibly smaller than 200 nm, and the process can be conducted continuously (Li 2007).

Direct Contact Membrane Distillation (DCMD)

Francesca Macedonio
Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy
Department of Environmental and Chemical Engineering, University of Calabria, Rende, Italy

Direct contact membrane distillation (DCMD) is one of the four main possible membrane distillation (MD) configurations. In DCMD process, an aqueous solution colder than the feed aqueous solution is maintained in direct contact with the permeate side of the membrane. Both the feed and permeate aqueous solutions are circulated tangentially to the membrane surfaces (Fig. 1). In this MD mode, the transmembrane temperature difference induces the required water vapor pressure difference between both membrane sides. Consequently, water molecules evaporate at the hot liquid/vapor interface, diffuse in vapor phase through the pores, and are condensed at the

pore-distillate interface on the other side of the membrane at a lower temperature (Fig. 2).

Among the possible MD configurations, DCMD is best suited for applications such as desalination or the concentration of aqueous solutions (orange juice), in which water is the major permeating component. Advantages and drawbacks of DCMD are similar to those of other MD configurations (see Membrane Distillation for a detailed description of benefits and disadvantages of DCMD) and summarized briefly as follows: theoretically 100 % rejection of nonvolatile solutes, lower operating temperature with respect to thermal evaporation processes, and reduced membrane fouling problem with respect to pressure-driven membrane processes, weakly influenced by feed concentration. Therefore, this thermal technique is relatively free from flux reduction by concentrating feed, which is inevitable in the reverse osmosis (RO)-based process. Consequently, the DCMD process is an appropriate alternative for achieving high water recovery from brackish/seawater feeds, managing the concentrate from desalination processes including RO and recovering water from industrial brines.

Heat and mass transfer phenomena occurring in DCMD process are discussed in various recent publications (Lawson and Lloyd 1997; Drioli et al. 2015; Schofield and Fane 1987; Martínez-Díez and Vázquez-González 2000; Gryta et al. 1997; Ali et al. 2013 and see “► Membrane Distillation (MD)”). The flux N can be represented by the following simple correlation:

$$N = C(P_{fm} - P_{pm})$$

where C is the membrane characteristic parameter and can be calculated by using various models, depending upon the membrane features and operating temperature applied. $\Delta P = P_{fm} - P_{pm}$ represents the vapor pressure difference across the membrane (function of temperatures and compositions at the membrane surface at feed f and permeate p side, respectively). Mass transfer in direct contact membrane distillation can be separated into three steps (e.g., mass transfer in feed

Direct Contact Membrane Distillation (DCMD), Fig. 1 Typical DCMD schema

Direct Contact Membrane Distillation (DCMD), Fig. 2 DCMD process

boundary layer, mass transfer across the membrane, and mass transfer in permeate boundary layer, as in *membrane distillation*). The mass transfer in permeate boundary layer is not taken into account since the mole fraction of the transporting species in the permeate stream is approximately equal to one. For what concerns the mass transfer in boundary layers, it is general to neglect surface diffusion and viscous flow and to employ a Knudsen-molecular diffusion transition model (Lawson and Lloyd 1997; Srisurichan et al. 2006).

For what concerns heat transfer, the net heat transported through conduction Q_c and due to evaporation Q_v in DCMD can be calculated by using the following relationships (Drioli et al. 2015):

$$Q = Q_c + Q_v = \frac{K_m}{\delta} (T_{fm} - T_{pm}) + J\lambda \quad (1)$$

at steady state

$$Q_f = Q_p \Rightarrow h_f (T_f - T_{fm}) = h_p (T_{pm} - T_p) \quad (2)$$

where Q_f and Q_p represent the heat transferred at bulk feed and permeate side, respectively. Moreover, each h and each T represent the corresponding heat transfer coefficients and temperatures shown in Fig. 2.

The real challenge is to calculate the temperatures at membrane surfaces (T_{fm} and T_{pm}). To realize this, various approaches have been used (Schofield and Fane 1987; Martinez-Diez and Vázquez-González 2000; Gryta et al. 1997). Schofield (Schofield and Fane 1987) suggests the following approach valid when transmembrane surface temperature differences are not greater than 10 °C. In this case the pure water flux can be represented by

$$N = C \frac{dP}{dT} \Big|_{T_m} (T_{fm} - T_{pm}) \quad (3)$$

where $\frac{dP}{dT} \Big|_{T_m}$ can be expressed according to Clausius-Clapeyron equation:

$$\frac{dP}{dT}|_{T_m} = \frac{M\lambda P}{RT^2}|_{T_m} \quad (4)$$

where M is the molar mass of water molecules. Assuming the same temperature polarization on up- and downstream,

$$T_m = \frac{T_f + T_p}{2} \quad (5)$$

Thus Eq. 1 can be written in the following form:

$$Q = \left(\frac{K_m}{\delta} + C \frac{dP}{dT}|_{T_m} \lambda \right) (T_f - T_{fm}) \quad (6)$$

$$Q = H (T_{fm} - T_{pm}). \quad (7)$$

Combining Eqs. 2, 6, and 7

$$(T_{fm} - T_{pm}) = \frac{T_f - T_p}{1 + \frac{H}{h_f} + \frac{H}{h_p}} \quad (8)$$

$$(T_{fm} - T_{pm}) = \theta (T_f - T_p) \quad (9)$$

from Eqs. 3 and 8,

$$\frac{\Delta T}{N\lambda} = \frac{1}{dP/dT} \frac{1}{\lambda C} \left(1 + \frac{K_m/\delta_m}{h} \right) + \frac{1}{h} \quad (10)$$

The permeability C and overall heat transfer coefficient h ($1/h_f + 1/h_p$) can be determined by plotting $\frac{\Delta T}{N\lambda}$ versus $\frac{1}{dP/dT}$ as illustrated by Eq. 10 (Drioli et al. 2015; Schofield and Fane 1987).

Equation 1 was originally developed for $T_{fm} - T_{pm} \leq 10^\circ\text{C}$ and for pure water as feed and permeate. A more general approach for the determination of up- and downstream heat transfer coefficients is based on the use of various empirical correlations. Recently some ambitious attempts have been observed in measuring the membrane surface temperature directly by using different techniques. For example, Ali et al. (2013) have used a cell equipped with 16 temperature sensors to measure the temperature profiles on feed and permeate side in DCMD. The effect of different parameters on thermal

polarization has been investigated by directly monitoring the bulk and interfacial temperatures. The authors have concluded that heat transfer coefficient can be predicted by using the relationship predicted by (Gryta et al. 1997).

Direct Contact Membrane Distillation (DCMD) Applications

Maria Tomaszewska

Faculty of Chemical Technology and Engineering, West Pomeranian University of Technology, Szczecin, Poland

DCMD is a membrane distillation (MD) configuration in which both solutions, feed and permeate, are in a direct contact with a hydrophobic porous membrane. Thus, the water vapor transferred across the membrane is directly condensed in a cold permeate inside the membrane module. This configuration has been the most frequently studied due to a simple operation mode in comparison with other MD configurations. DCMD is

Direct Contact Membrane Distillation (DCMD) Applications, Fig. 1 Scheme of sea water desalination plant using integrated membrane system containing membrane

crystallization units operating on the brine from NF and/or RO stages (Based on Di Profio et al. (2010)).

considered as the best choice for applications in which water is the major component of the feeding solution. DCMD can be applied in chemical, food, or pharmaceutical industry and in environmental protection.

The major area of DCMD application is desalination focused on the production of high purity water and freshwater from sea or brackish water. The nature of DCMD driving force causes that nonvolatile solutes such as salts, colloids, and macromolecules that are almost completely retained by a membrane. The permeate is pure water with electrical conductivity of 0.2–2.5 $\mu\text{S}/\text{cm}$, which is suitable for medical, pharmaceutical, or semiconductor industry purposes. Lower temperatures than those usually used in the conventional distillation allow to achieve the permeate fluxes up to 80 $\text{kg}/\text{m}^2\text{h}$ with significant reduction in energy costs. Typical feed temperatures (30–80 $^{\circ}\text{C}$) permit the efficient recycle of low-grade or waste heat streams, as well as the use of alternative energy sources (solar, wind, or geothermal). In addition, the possibility of using plastic equipment also reduces corrosion problems (Drioli et al. 2005; Khayet and Matsuura 2011).

Integration of DCMD with pressure-driven membrane processes such as microfiltration (MF) or reverse osmosis (RO) creates the opportunity for enhancement of water productivity from seawater up to 87.6 %. A development of the system coupling nanofiltration (NF) and RO with DCMD/membrane crystallizer (MCr) might lead to an increase in the total water recovery factor of a desalination plant up to 92.8 %

(Fig. 1). An application of the DCMD/MCr system allows to recover both water and salts (commercial products), reducing the environmental problems related to brine disposal (Drioli et al. 2011; Di Profio et al. 2010).

A DCMD system utilizing solar and wind energy for water supply, designed for small board and rural or coastal areas with a lack of electricity, is presented in Fig. 2 (Susanto 2011).

DCMD has also been applied to surface or groundwater treatment. It was found that membrane scaling by CaCO_3 , CaSO_4 , and their mixture occurring in the system can be significantly limited by the feed acidification or antiscalant addition. Moreover, it was found that scaling in DCMD is less severe than in conventional desalination processes (Khayet and Matsuura 2011).

DCMD can be operated with solutions of extremely high concentration of salts, even close to the supersaturated point, and the permeate flux was satisfying. Therefore, DCMD has also been successfully applied to wastewater treatment, either to produce a permeate less hazardous to the environment or to obtain a retentate that contains high concentration of valuable chemicals (Table 1) (Khayet and Matsuura 2011).

The main disadvantage of DCMD process is a problem with membrane wetting, what limits the concentration of organic compounds to diluted aqueous solutions. The membranes used in MD are chemically resistant; thus, they can tolerate harsh operating conditions. DCMD is a promising method for recovery of HCl from metal pickling

Direct Contact Membrane Distillation (DCMD) Applications, Fig. 2 Schematic diagram of DCMD powered by solar and wind energy (Reprinted from Susanto (2011), copyright (2011), with permission from Elsevier)

Direct Contact Membrane Distillation (DCMD) Applications, Table 1 Examples of DCMD application in various fields

Application area	Examples of application
Water treatment	Desalination of seawater and brackish water, removal of various contaminants (heavy metals, arsenic, boron, humic acid) from surface and groundwater, production of high purity water, removal of low concentrations of organics (ethanol, acetone, acetonitrile, n-butanol)
Wastewater treatment	Treatment of low- and medium-level radioactive wastewater, textile wastewater contaminated with dyes, oil-water emulsions, HCl removal from etching solutions from electrochemical industry, separation of photocatalyst in the photocatalysis-DCMD system, reclamation in space
Medicine and biology	Concentration of an extract of traditional Chinese medicine Concentration of bovine plasma and bovine blood, bovine serum albumin, to ameliorate treatment of uremia
Pharmacy	Pharmaceutical wastewaters containing taurine
Food industry	Concentration of fruit and juices, whey, sugarcane, etc.
Biotechnology	Removal of toxic products from culture broth, production of ethanol in a bioreactor-DCMD system
Chemical industry	Concentration of acids, separation of a half-finished product (HCl) from the reaction mixture to shift the reaction equilibrium in DCMD-chemical reactor system
Other	Ethylene glycol removal from coolant liquids, breaking azeotropic mixtures HCl-water, propionic acid-water, salt crystallization in DCMD/MCr

Direct Contact Membrane Distillation (DCMD) Applications, Fig. 3 The flow – sheet diagram of integrated processes of metal pickling with treatment of spent

solution using DCMD (Reprinted from Tomaszewska et al. 2001, copyright (2001) with permission from Elsevier)

Direct Contact Membrane Distillation (DCMD) Applications, Fig. 4 Scheme of the conversion of potassium chloride into potassium sulfate using integrated system: chemical reactor/DCMD (Based on Tomaszewska and Mientka 2009)

solutions (Fig. 3) (Tomaszewska et al. 2001). The process was also successfully applied in a pilot scale to clean low- and medium-level radioactive waste from a nuclear center.

Moreover, DCMD found success in the treatment of solutions containing substances sensitive to high temperature due to the risk of their degradation, especially in biotechnology and food

industry (fruit juices concentration) (Sotoft et al. 2012).

Novel applications are bio- and chemical reactors integrated with DCMD in which the volatile products are continuously removed from the reaction mixture to shift the equilibrium and improve productivity. It was found that a continuous extraction of ethanol from broth using DCMD

resulted in an increase of its productivity by 87 % (Khayet and Matsuura 2011). The membrane reactor based on DCMD was applied in the production of potassium sulfate for fertilizer industry (Tomaszewska and Mientka 2009). The concentration of the reaction mixture containing KCl and K_2SO_4 close to the saturated state in the membrane reactor resulted in periodical precipitation of $KHSO_4$, whereas HCl was continuously removed from the reaction mixture to shift the equilibrium of the conversion (Fig. 4).

MD is generally recommended for special purposes for which the application of other membrane techniques was considered impossible. Until now the DCMD process has been under development due to high energy consumption and problems with the membrane wettability during long-time operation. However, it should be pointed out that there are numerous calculations showing that DCMD can be economically attractive especially when low-grade energy or alternative energy is used.

Direct Fluorination of Polymer Membranes: Gas Separation Properties

A. P. Kharitonov

Talrose Branch of the Institute of Energy Problems of Chemical Physics of the Russian Academy of Sciences, Moscow Region, Russia

Polymeric membranes can be used for the separation of gas mixtures such as $He-CH_4$, H_2-CH_4 , CO_2-CH_4 , H_2-N_2 , etc. There is, however, a common problem in a gas separation when a polymeric membrane is used: membranes with high gas permeability often have low gas separation factor, and on the contrary, membranes with high separation factor have low permeability (Fig. 1) (Robeson 2008). The direct fluorination can be effectively used to improve gas separation

Direct Fluorination of Polymer Membranes: Gas Separation Properties, Fig. 1 Separation selectivity α for the He/CH_4 mixture vs. permeability of He for various polymer membranes in logarithmic scale. Filled points – literature data (Robeson 2008). Empty triangle, square, and diamond correspond to pristine polyamide Matrimid® 5218 hollow fiber module (points correspond to different treatment conditions) and PVTMS (Kharitonov 2007, 2008) and PTMSP (Langsam et al. 1988) flat membranes. Filled symbols represent transport properties of fluorine treated membranes

properties of polymer membranes when the gas mixture consists of gases with markedly different gas kinetic diameters. In this case substantial increase of separation selectivity (up to several tens times for the case of He/CH₄ mixture) is accompanied with a relatively small decrease (or no change) of permeability of a gas with smaller gas kinetic diameter (He, H₂, etc.). Direct fluorination of polymers is a heterogeneous reaction of gaseous F₂ mixtures with a polymer surface. This is a method of the surface modification: only upper surface layer is modified (~0.01 to several microns in thickness), but the bulk properties (e.g., tensile strength) remain unchanged. The direct fluorination proceeds spontaneously at room temperature with sufficient for industrial applications rate. Fluorination results in a substitution of H-atoms for F-atoms, saturation of double (conjugated) bonds with fluorine, and disruption of majority of C-N and C-Si bonds followed with formation of C-F bonds. The chemical composition of fluorinated layer depends on composition and pressure of fluorinating mixture and treatment duration. Treatment at mild fluorination conditions does not cause disruption of C-C bonds in the main polymer chain. Direct fluorination is a dry technology. Polymer hollow fibers, fabricated membrane modules, and composite membranes can be treated. For the case of hollow fibers and composite membranes, only the dense separation layer can be fluorinated and the porous support will remain untouched, so the tensile strength of membrane element will not be decreased. There are safe and reliable methods to neutralize (by converting into the solid phase) unused F₂ and the end product HF.

The direct fluorination was used to enhance gas separation properties of several polymer membranes (both homogeneous and composite) and hollow fiber modules: polyimide (PI), polyvinyltrimethylsilane (PVTMS), poly(1-trimethylsilylpropyne) (PTMSP), poly(phenylene oxide), polysulfone, poly(4-methylpentene), polycarbonatesiloxane, etc. (Langsam et al. 1988; Le Roux et al. 1994; Amirkhanov et al. 1998; Kharitonov 2007, 2008). Figure 1 illustrates the influence of direct fluorination on separation selectivity for He/CH₄ mixture. As it is

Direct Fluorination of Polymer Membranes: Gas Separation Properties, Fig. 2 Influence of treatment conditions of PVTMS flat membrane on the separation selectivity of CO₂/CH₄, He/N₂, and He/CH₄ mixtures. Treatment condition (from left to right in each group at the plot): virgin PVTMS, treatment with 2 % F₂ + 98 % He mixture, treatment with 33 % F₂ + 67 % He mixture, treatment with 2 % F₂ + 98 % He mixture followed by a grafting of acrylonitrile, treatment with 60 % F₂ + 40 % O₂ mixture

evidenced by Fig. 1, direct fluorination results in a very remarkable increase (by a factor of several tens times or more than hundred times) of separation selectivity. The permeability of He and H₂ is not practically changed after fluorination. Hence the direct fluorination of PVTMS and polyimide Matrimid 5218 provides the possibility to “overjump” the Robeson boundary (straight line in Fig. 1). The direct fluorination can substantially improve the separation selectivity of CO₂/CH₄, He/N₂ and He/CH₄ mixtures (Fig. 2).

Direct Membrane Emulsification

Emma Piacentini¹, Alessandra Imbrogno^{1,2} and Richard G. Holdich³

¹Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

²University of Calabria, Rende, Italy

³Department of Chemical Engineering, Loughborough University, Loughborough, Leicestershire, UK

In the early 1990s, Nakashima and Shimizu (1991) introduced membrane technology for emulsion preparation by the *direct emulsification method* (DME). In DME, the dispersed phase is directly fed through the membrane pores and emulsion droplet formation takes place on the other side of the membrane, which is in contact with the continuous phase (Fig. 1). Here, droplets can detach after reaching a critical dimension either for spontaneous deformation (*Static*

Direct Membrane Emulsification, Fig. 1 Direct membrane emulsification method

Membrane Emulsification), or as a consequence of the shear stress generated by moving the membrane or the continuous phase (*Dynamic Membrane Emulsification*).

Usually, in the DME method, the membrane is wetted by the continuous phase, and hydrophilic and hydrophobic membranes are used in the preparation of oil-in-water (O/W) and water-in-oil (W/O) emulsions, respectively. The mean emulsion droplet size is controlled by the appropriate selection of the pore size of the membrane, and a factor of 2–10 is found between pore size and droplets size. Additional parameters have to be considered to tune the production of an emulsion by DME:

- Shear stress. Uniform and small droplets are obtained when the shear stress increases as a consequence of their faster detachment at the membrane pore surface. In general, the mean droplet size decreases exponentially until it reaches a size where it becomes, more or less, independent of the applied shear. The shear stress can be produced: (i) by flowing the continuous phase tangentially to the membrane surface (cross-flow ME), (ii) by pulsating the continuous phase in the lumen side of the membrane (pulsed ME or pulsed back-and-forward ME), (iii) by rotating or vibrating the membrane, and (iv) by inducing azimuthal oscillation of a tubular membrane.
- Transmembrane pressure. The transmembrane pressure needs to be higher than a critical pressure (capillary pressure) in order to initiate dispersed phase intrusion in the pores. The dispersed phase flux increases with an increase of the transmembrane pressure as more pores are gradually activated for droplet production and the velocity increases in the pores. Larger droplets are produced at higher dispersed phase flux.
- Emulsifier. Droplet size decreases with lower interfacial tension and, according to the time needed by the emulsifier, is dissolved in the dispersed phase to cover the forming droplet surface area. Smaller droplets are produced because of a faster decrease of retaining forces and a reduction of coalescence between the forming droplets at adjacent pores.

One of the main limitations of DME is the low dispersed phase flux through conventional matrix-type membranes (like SPG or ceramic membranes) which have high thickness and tortuous pore channels giving relatively high flow resistance. As an alternative, higher dispersed phase flux at low transmembrane pressure can be achieved using microsieve-type membranes due to their low thickness and well-defined rectilinear pores. Another problem encountered when the amount of the dispersed phase emulsified is increased is the recirculation of the continuous phase (including emulsion drops), giving rise to poor control over the droplet size distribution. This is due to the interactions of the newly forming droplets with droplets in the emulsion, as well as droplet breakup within the circuit. To overcome this problem, advanced methods for dynamic membrane emulsification like rotating, vibrating, azimuthally oscillating membrane emulsification, and pulsed flow have received much attention.

The DME method is suitable for the preparation of simple and multiple emulsions as well as polymeric particles. In the latter case, polymerization, gelation, or coacervation processes of the formed droplets are carried out subsequently to droplet generation.

Direct Methanol Fuel Cell (DMFC)

Antonino Salvatore Arico
CNR-ITAE Institute, Messina, Italy

The core of a direct methanol fuel cell is a polymer electrolyte ion-exchange membrane. The electrodes (anode and cathode) are in intimate contact with the membrane faces. A scanning electron

micrograph of a DMFC MEA is shown in Fig. 1 (Aricò et al. 2001). The electrodes usually consist of three layers: catalytic layer, diffusion layer, and backing layer. The catalytic layer is composed of a mixture of catalyst and ionomer, and it is characterized by a mixed electronic-ionic conductivity. The catalysts are often based on carbon-supported or carbon-unsupported PtRu and Pt materials at the anode and cathode, respectively. The membrane as well as the ionomer consists, in most cases, of a perfluorosulfonic acid polymer. The package formed by electrodes and membrane is called “membrane and electrode assembly” (MEA). The overall thickness of this package is generally smaller than 1 mm. Each MEA forms a cell. Several cells are usually connected in series to form a fuel cell stack that is integrated in a system which contains the auxiliaries allowing stack operation and delivering of the electrical power to the external load.

Typical perfluorosulfonic acid membranes used in the present DMFCs, such as Nafion (DuPont), are permeable to methanol transport (Ren et al. 1996), thereby reducing significantly the fuel utilization efficiency of the device. A scheme of the overall reaction process occurring in a DMFC equipped with a proton-conducting electrolyte is outlined below:

In the presence of an alkaline electrolyte, the process is outlined as follows:

Direct Methanol Fuel Cell (DMFC), Fig. 1 SEM micrograph of a DMFC membrane and electrode assembly equipped with Nafion 112 membrane

D

Direct Methanol Fuel Cell (DMFC), Fig. 2 Single-cell and in situ half-cell electrode polarizations for a DMFC operating at 60 °C, ambient pressure, with 1 M methanol at the anode and air feed at the cathode

The thermodynamic efficiency of the process is given by the ratio between the Gibbs free energy, i.e., the maximum value of electrical work (ΔG°) that can be obtained, and the total available energy for the process, i.e., the enthalpy (ΔH°). Under standard conditions:

$$\eta_{\text{rev}} = \Delta G^\circ / \Delta H^\circ; \text{ reversible energy efficiency} \quad (6)$$

with

$$\Delta G^\circ = \Delta H^\circ - (T \cdot \Delta S^\circ) \quad (7)$$

and

$$\Delta G^\circ = -nF \cdot \Delta E_{\text{rev}} \quad (8)$$

ΔE_{rev} is the electromotive force. At 25 °C and 1 atm and with pure oxygen feed, the reversible potential for methanol oxidation is 1.18 V (Aricò et al. 2001). It does not vary significantly in the operating range 20–130 °C and 1–3 bar abs. pressure.

Usually, the open-circuit voltage of a polymer electrolyte direct methanol fuel cell is significantly lower than the thermodynamic or reversible potential for the overall process (Fig. 2). This is mainly due to methanol crossover that causes a mixed potential at the cathode and to the

irreversible adsorption of intermediate species at electrode potentials close to the reversible potential. Direct methanol fuel cells find application in portable power sources, assisted power units (APU), and electrotraction (Dillon et al. 2004).

Discontinuous Diafiltration by Sequential Dilution (Sequential Dilution Diafiltration)

Greg Foley

School of Biotechnology, Dublin City University, Dublin, Ireland

Discontinuous diafiltration by the sequential dilution method can be summarized in terms of the three steps shown below. The apparent rejection coefficients are assumed to be 1.0 and 0 for macrosolute and microsolite, respectively.

Step 1: Add buffer to increase solution volume from V_0 to V_f . *Macrosolute (A) and microsolite (B) concentrations decrease.*

Step 2: Use batch ultrafiltration to reduce solution volume back from V_f back to V_0 . *Macrosolute concentration returns to its initial value, microsolite concentration remains unchanged. (This follows from the rejection coefficients of both solutes.)*

Step 3: Repeat steps 1 and 2 as required.

A microsolite balance on the first step gives

$$\beta = c_{B0}/c_{Bf} = V_f/V_0$$

Extending this analysis to n stages (i.e., repeating steps 1 and 2 above n times) gives

$$V_f/V_0 = \beta^{1/n}$$

For example, if the microsolite concentration is to be reduced by a factor of 10 ($= \beta$) and then if a single stage is used, $V_f/V_0 = 10$, while if three stages are used, $V_f/V_0 = 10^{1/3} = 2.15$.

The total volume of buffer used in this case is given by

$$\begin{aligned} V_b/V_0 &= n(V_f - V_0)/V_0 = n(V_f/V_0 - 1) \\ &= n(\beta^{1/n} - 1) \end{aligned}$$

For a single stage system, this ratio works out as 9, while for a three-stage system, it works out as 3.46. Thus, the more stages that are used, the smaller the buffer consumption.

Discontinuous Diafiltration by Volume Reduction (Intermittent Feed Diafiltration)

Greg Foley

School of Biotechnology, Dublin City University, Dublin, Ireland

The steps involved in a discontinuous diafiltration by volume reduction ([► intermittent feed diafiltration](#)) are outlined below. The apparent rejection coefficient of the macrosolute is 1.0, while that of the microsolite is zero.

Step 1: Batch ultrafiltration from volume V_0 to V_f . *Macrosolute concentration increases, microsolite concentration remains the same because it has a rejection coefficient of zero.*

Step 2: Replace lost permeate with diluant (pure water or buffer). *Macrosolute concentration returns to initial concentration, microsolite concentration reduced.*

Step 3: Repeat steps 1 and 2 as required.

Consider a single “stage,” i.e., steps 1 and 2 above. The concentration of the macrosolute remains unchanged. A mass balance on the microsolute gives the following expression for its concentration at the end of the two-step process.

$$\beta = c_{B0}/c_{Bf} = V_f/V_0$$

If this is repeated n times, one gets

$$V_0/V_f = \beta^{1/n}$$

The buffer consumption is given by

$$\begin{aligned} V_b/V_0 &= n(V_0 - V_f)/V_0 = n(1 - V_f/V_0) \\ &= n(1 - \beta^{-1/n}) \end{aligned}$$

Thus, for a tenfold reduction in microsolute concentration and a three-stage process, one gets $V_0/V_f = 10^{1/3} = 2.15$ in each step, while the buffer consumption works out as $V_b/V_0 = 3(1 - 10^{-1/3}) = 1.607$.

If one stage had been used, one would have had $V_0/V_f = 10$ and $V_b/V_0 = 1.0(1 - 10^{-1}) = 0.9$. Thus, increasing the number of stages increases the amount of buffer required.

The single-stage approach is not always possible as too large a [volume concentration factor](#) (V_0/V_f) might lead to unsustainably high solution viscosities.

Dissolved Oxygen (DO) in Water by Membrane Operations, Removal of

V. V. Volkov

A.V. Topchiev Institute of Petrochemical Synthesis Russian Academy of Sciences (TIPS RAS), Moscow, Russian Federation

Dissolved oxygen (DO) is one of the principal components which should be removed for the production of ultrapure water. Even though concentration of DO in water is very low

(approximately 8 ppm under ambient conditions), DO leads to oxidation of dissolved components and materials, for example, boiler piping in (nuclear) power plants. In such systems, the desired DO concentration in the boiler feed water is 7–10 ppb. Therefore, DO removal from water presents a challenging problem for various industries such as production of semiconductors, power plants, pharmaceuticals, and biotechnology. In the production of semiconductors, standard DO level in ultrapure water is the most stringent (below 1 ppb). Removal of DO from water by membrane technology can be accomplished by using gas-liquid *membrane contactors* and *membrane reactors*.

Gas-liquid membrane contactors generally incorporate a porous hollow fiber membrane for direct contacting of two immiscible phases, namely, a gas and a liquid, for the purpose of absorption or stripping without dispersion of one phase into another. The DO removal from water on a membrane contactor requires generation of a driving force for oxygen transmembrane transfer, and this process demands reduction in oxygen concentration in a gas phase. This goal can be accomplished in one of three ways: (1) by applying vacuum to the water, (2) by supplying an appropriate sweep gas to the gas side, and (3) by a combination of the first two where a small flow of sweep gas is used to improve separation driving force but the gas side is still maintained under vacuum (Sengupta et al. 1998). In industrial (commercial) Liqui-Cel[®] gas-liquid membrane contactors, polypropylene porous hollow fiber membranes are used. These membrane contactors offer a serious alternative to the traditional two-stage vacuum degassing towers in the high-purity water treatment systems in the semiconductor industry.

DO removal from water can be performed on a membrane-UV reactor because DO can react with hydrogen to yield water under the action of UV irradiation with a wavelength of 185 nm. This reaction requires dissolution of hydrogen in water, and this process is provided by gas-liquid membrane contactors based on hollow fiber membranes which are permeable for hydrogen and UV irradiation (Li and Tan 2001).

Most efficient existing methods for deep removal of DO from water are based on the principle of oxygen reduction by hydrogen on a palladium catalyst which yields water. The existing catalytic processes for water deoxygenation via hydrogenation reaction involve two stages: (1) absorption of hydrogen in water and (2) passage through a fixed-bed catalytic reactor. In contrast to existing processes, the DO removal on a catalytic membrane reactor can be accomplished in one stage. There are two configurations of catalytic membrane reactors. The first design of the membrane reactor is based on a polypropylene porous hollow fiber membrane module packed with a palladium catalyst, namely, spherical beds of palladium-deposited granules of anion-exchange resin in the void space of the shell side (Li et al. 1995). An alternative design of a catalytic membrane reactor provides *water deoxygenation by catalytic membranes*, namely, by *palladium-loaded hollow fibers* (Volkov et al. 2009). Water and hydrogen are supplied into a shell side of the reactor and into a fiber lumen, respectively. Hence, DO removal is accomplished by chemical reaction between dissolved oxygen and dissolved hydrogen in the presence of the palladium-based catalyst. Using a catalytic membrane reactor, concentration of DO in water of ten parts per billion (ppb) and lower is feasible.

Distributor Reactor

► Membrane Distributor

Donnan Effect

Patrick Fievet

Institut UTINAM, University of Franche-Comté, Besançon, France

The Donnan effect (which is named after the British chemist Frederick George Donnan (Donnan 1911, 1995) is related to the presence of impermeant ions (i.e., ions that are unable to pass through a semipermeable membrane or boundary) upon one side of a boundary on the distribution of permeant ions across the boundary. At equilibrium, the co-ions (i.e., ions with the same charge polarity as the impermeant ions) will be less concentrated on the impermeant ions' side of the boundary than the other side, whereas the counterions (i.e., ions having the charge polarity opposite to that of the impermeant ions) will be more concentrated there. It results an unequal distribution of permeant ions between the two sides of the boundary.

The surface charged groups (e.g., sulfonic or carboxylic acids) of a synthetic membrane are an example of impermeant ions. When such a membrane is placed in a salt solution, a Donnan equilibrium sets up at both membrane-external solution interfaces. Because of the presence of the membrane fixed charge, the ion concentrations in the membrane are not equal to those in the solution: the concentration of co-ions is lower in the membrane phase than in the solution, while the concentration of counterions is higher there. A potential difference, called the Donnan potential, is created at the membrane-solution interface to counteract the transport of the co-ions to the membrane phase and the transport of counterions to the solution. In other words, the co-ions are repelled by the membrane, whereas the counterions are attracted.

D

Donnan Effect, Fig. 1 (a) Schematic representation of the distribution of cations C and anions A between the solution and the membrane having fixed ionic groups G; (b) Donnan relation and electroneutrality conditions in the solution and membrane. c and $\bar{c}$ are the molar ion concentration at equilibrium in the solution and membrane, respectively. v_+ and v_- are the stoichiometric coefficients

of cations and anions, respectively. z_C and z_A are the charge numbers of cations and anions, respectively. The symbol X (positive or negative depending on the charge sign of the membrane) denotes the volume charge density, which is defined as the number of moles of fixed charges per unit of pore volume

To illustrate the influence of various parameters on the Donnan equilibrium, let us consider the equilibrium situation between a membrane containing fixed ionic groups G and an ionic solution containing the strong electrolyte CA (Fig. 1).

Based on the Donnan equilibrium and taking the electroneutrality conditions into account, the partitioning coefficient of co-ions at the membrane-solution interface ($k_{\text{co-ion}}$), which describes the distribution of co-ions between the membrane and the solution, can be derived:

$$k_{\text{co-ion}} = \frac{\bar{c}_{\text{co-ion}}}{c_{\text{co-ion}}} = \left(\frac{z_{\text{co-ion}} c_{\text{co-ion}}}{z_{\text{co-ion}} \bar{c}_{\text{co-ion}} + X} \right) \left(\left| \frac{z_{\text{co-ion}}}{z_{\text{counterion}}} \right| \right) \quad (1)$$

with $c_{\text{co-ion}}$ and $\bar{c}_{\text{co-ion}}$ the concentrations of co-ions in the solution and membrane, respectively, and $z_{\text{co-ion}}$ and $z_{\text{counterion}}$ the charge numbers of co-ions and counterions, respectively.

A co-ion partitioning coefficient that tends to one means that co-ions (and therefore counterions due to electroneutrality requirements) are only slightly excluded from the membrane (weakly charged membrane, small $|X|$), whereas a co-ion partitioning coefficient that tends to zero means that the co-ions are strongly excluded from the membrane (strongly charged membrane, high $|X|$).

Donnan Effect, Table 1 Calculation of the co-ion partitioning coefficient ($k_{\text{co-ion}}$) at a membrane-solution interface for a (positively or negatively charged) membrane with a fixed charge $|X|$ of $10^{-2} \text{ mol L}^{-1}$ and various salts and concentrations

$c_{\text{co-ion}} (\text{mol L}^{-1})$	$ z_{\text{co-ion}} $	$ z_{\text{counterion}} $	$k_{\text{co-ion}}$
10^{-4}	1	1	0.01
10^{-3}	1	1	0.10
10^{-2}	1	1	0.62
10^{-3}	1	2	0.31
10^{-3}	2	1	0.04

Solving Eq. 1 allows the concentration of co-ions in the membrane ($\bar{c}_{\text{co-ion}}$) and, thus, the partitioning coefficient of co-ions ($k_{\text{co-ion}}$) to be calculated. Results presented in Table 1 show that exclusion increases ($k_{\text{co-ion}}$ decreases) when:

- The salt concentration (or $c_{\text{co-ion}}$) decreases
- The charge number of co-ions $z_{\text{co-ion}}$ increases
- The charge number of counterions $z_{\text{counterion}}$ decreases
- The fixed membrane charge (in absolute value) X increases.

The increase (in absolute value) in the fixed charge and electrolyte concentration has then opposite effects on the exclusion phenomenon since the former makes the Donnan effect stronger, whereas the latter screens the electrostatic interaction between ions and the membrane fixed

Donnan Effect, Table 2 Calculation of the co-ion partitioning coefficient ($k_{\text{co-ion}}$) at a membrane-solution interface for various membrane volume charges $|X|$, salts, and concentrations

Salts	c_{salt} (mol L^{-1})	$Z_+ V_+$ $c_{\text{salt}} = Z_- V_-$ c_{salt}	$ X $ (mol L^{-1})	$\frac{ X }{Z_+ V_+ c_{\text{salt}}}$	$k_{\text{co-ion}}$
1:1	10^{-3}	10^{-3}	10^{-2}	10	0.10
1:1	10^{-2}	10^{-2}	10^{-1}	10	0.10
1:2	5×10^{-4}	10^{-3}	10^{-2}	10	0.01
1:2	5×10^{-3}	10^{-2}	10^{-1}	10	0.01
2:1	5×10^{-4}	10^{-3}	10^{-2}	10	0.31
2:1	5×10^{-3}	10^{-2}	10^{-1}	10	0.31
2:2	5×10^{-4}	10^{-3}	10^{-2}	10	0.10
2:2	5×10^{-3}	10^{-2}	10^{-1}	10	0.10

Salt 1:2: salt with a monovalent counterion and divalent co-ion
Salt 2:1: salt with a divalent counterion and monovalent co-ion
Salt 1:1: salt with a monovalent counterion and monovalent co-ion
Salt 2:2: salt with a divalent counterion and divalent co-ion

charge. As a result, as can be seen in Table 2, the co-ion partitioning coefficient is ruled by the ratio of the membrane fixed charge (in absolute value) to the charge concentration in solution, $\frac{|X|}{Z_+ V_+ c_{\text{salt}}}$. Table 2 also shows that for salt solutions having the same charge concentration, the co-ion partitioning coefficients are identical for salts 1:1 and 2:2, and $k_{\text{co-ion}}$ follows the sequence $2:1 > 1:1 = 2:2 > 1:2$ where the first figure denotes the charge number of the counterion and the second one that of the co-ion.
